## Abstract

Structural and dynamic perturbations in DNA upon incorporation of either fluorophore, 2-Aminopurine (2AP) or 2-Hydroxy-7-nitrofluorene (HNF), are characterized by NMR spectroscopy. For this purpose the NMR solution structures of the modified DNA duplexes with the sequence 5'-GCTGCAXACGTCG-3' are solved. For X=2AP (13mer2AP) the partner base in the complementary strand is T, while for X=HNF (13merHNF) an abasic site is introduced to avoid steric strain.

By comparing results on 13mer2AP with the corresponding unmodified DNA duplex (13merRef, X=A), any perturbation can be unambiguously assigned to 2AP incorporation. For the NMR solution structure of 13merRef and 13mer2AP small but significant changes in helical parameters are found throughout the helix. Imino proton exchange measurements reveal an extended, distributed effect of 2AP incorporation on the lifetimes of the central seven base pair. However, the reduced base pair lifetime of 2AP:T cannot fully account for the rapid water exchange observed with saturation transfer experiments in the absence of base catalyst. This indicates enhanced intrinsic catalysis. As a possible catalytic site the T O4 atom opposite 2AP is discussed, which is easily accessible through the major groove and lacks a hydrogen bonding partner within the base pair.

The overall NMR solution structure is found to be B-DNA. However the NOE cross-peaks involving the HNF residue can only be accounted for by two different orientations of the HNF inside the DNA helical stack. Their population ratio is estimated to be 1:1. Dynamical perturbation is indicated by the increased linewidth and strong upfield shift of the T residue to the 5'-side of the abasic site.

## Zusammenfassung

Mittels NMR-Spektroskopie werden Störungen in Struktur und Dynamik von DNA untersucht, die durch den Einbau jeweils eines der beiden Fluorophore 2-Aminopurin (2AP) und 2-Hydroxy-7-nitrofluoren (HNF) hervorgerufen werden. Zu diesem Zweck werden die NMR-Strukturen der modifizierten Duplexe mit der Sequenz 5'-GCTGCAXACGTCG-3' berechnet. Im Fall  $X=2AP$  (13mer2AP) ist die Partnerbase im Komplementärstrang ein T, während gegenüber  $X=HNF$  (13mer-HNF) eine abasische Stelle eingeführt wird.

Durch den Vergleich der Ergebnisse zum 13mer2AP mit denjenigen des entsprechenden unmodifizierten DNA Doppelstranges (13merRef,  $X=A$ ) konnte jegliche Änderung eindeutig dem Einbau von 2AP zugeordnet werden. Für die NMR-Strukturen von 13merRef und 13mer2AP können kleine aber signifikante, über die gesamte Helix verteilte Strukturstörungen nachgewiesen werden. Experimente zum Iminoprotonenaustausch mit Wasser ergeben, daß der Einbau von 2AP die Basenpaarlebensdauern der 7 zentralen Basenpaare erniedrigt. Die kürzere Lebensdauer des 2AP:T Basenpaares kann jedoch nicht den schnellen Wasseraustausch im Sättigungstransfer-Experiment ohne Zugabe von Basenkatalysator erklären. Als Erklärung für diese Diskrepanz wird eine effizientere intrinsische Katalyse vermutet. Als mögliche, katalytisch aktive Stelle wird das T O4 Atom diskutiert, welches über die große Furche leicht zugänglich ist und das keine Wasserstoffbrückenbindung innerhalb des Basenpaares ausbilden kann.

Die übergeordnete Struktur des 13merHNF ist eine B-Form DNA Helix. Die NOE Kreuzpeaks zu den Protonen im HNF können jedoch nur durch zwei verschiedene Orientierungen des HNFs in der helikalen Anordnung beschrieben werden. Das Verhältnis der beiden Orientierungen untereinander wird als 1:1 abgeschätzt. Störungen in der Basenpaardynamik werden durch die höhere Linienbreite und die starke Hochfeldverschiebung des T auf der 5'-Seite ausgehend von der abasischen Stelle angedeutet.

Mein besonderer Dank gilt Herrn Professor Doktor Nikolaus P. Ernsting. Über die normale Betreuung bei einer Dissertation hinaus half er mir jederzeit engagiert bei der Lösung nicht nur fachlicher Probleme. In unseren fachlichen Diskussionen hat er mich immer wieder zur Äußerung eigener Ideen ermutigt und dabei großes Vertrauen in mein Können gesetzt. Das wissenschaftliche Arbeiten war so nicht nur ein Pflichtprogramm, sondern gleichzeitig ein Hobby. Durch die Freiheit in Bezug auf Arbeits- und Zeiteinteilung, die er mir gewährte, trug er in hohem Maße dazu bei, daß ich Arbeit und Familie vereibaren konnte. Dafür bin ich Herrn Professor Ernsting außerordentlich dankbar.

Herrn Professor Doktor Christian Griesinger danke ich für seine großzügige Unterstützung und seine vielen hilfreichen Anregungen, die mir wichtige Impulse für meine Arbeit lieferten.

Herr Professor Doktor Clemens Mügge hat mir viel am und um das NMR-Spektrometer und mit vielen hilfreichen Hinweisen und Diskussionen geholfen. Ohne seinen Einsatz und seine Flexibilität bei der Meßzeiteinteilung, hätte ich meine Arbeit nicht in so kurzer Zeit durchführen können.

Mein Dank gilt ferner Frau Doktor Jennifer Tuma, die mir den Einstieg in die Thematik der NMR-Strukturanalytik sowie die Handhabung eines NMR-Gerätes sehr erleichterte.

Ich möchte mich auch ganz herzlich bei Herrn Diplom-Chemiker Lars Dehmel bedanken, der - trotz eigener Doppelbelastung durch Kind und Diplomarbeit - die Zeit fand, mit mir mehrere Tage hintereinander im Institut zu "campieren", um die NMR-Titration zu optimieren. Desweiteren machte er sich um die Auswertung dieser Messungen durch das Schreiben mehrerer Skripte sehr verdient.

Herrn Doktor Horst Hennig danke ich für die große Hilfe in vielen formalen Angelegenheiten und darüber hinaus. Frau Iris Suter bzw. Frau Sabrina Penn und Frau Heiderose Steingräber möchte ich herzlich danken, da sie stets sehr hilfsbereit waren und ein offenes Ohr für die kleinen Probleme des (wissenschaftlichen) Alltags hatten.

## *Inhaltsverzeichnis*

Mein Dank gilt auch den restlichen Mitgliedern der Arbeitsgruppe Ernsting – Herrn Doktor Sergej Kovalenko, Herrn Doktor Alexander Dobryakov, Herrn Doktor Luis P. Lustres, Herrn Diplom-Chemiker Alexander Weigel – für die Unterstützung und die vielen Hilfestellungen beim Arbeiten.

Bei Herrn Diplom-Chemiker Patrick Wilke möchte ich mich für die Unterstützung im Rahmen seines Forschungspraktikums und darüber hinaus bedanken.

Meinen Eltern und meinen Schwiegereltern danke ich für die große Hilfe bei der Betreuung meiner Kinder, durch die ich so intensiv an dieser Dissertation arbeiten konnte. Ihre Anteilnahme und ihre (wissenschaftlichen) Ratschläge haben mich ermutigt und motiviert. Auch für die finanzielle Unterstützung bin ich ihnen sehr dankbar.

Amélie und Tristan - ihr seid meine größten Schätze. Ich liebe Euch.

# 1 Introduction

In 1953 Watson and Crick (WC) solved the puzzle of the deoxyribonucleic acid (DNA) structure [Watson and Crick, 1953]. Aided by the results of Chargaff [1950] and Franklin and Gosling [1953] they proposed the double helical structure. Since then the double helical arrangement of DNA has become common knowledge. But although the overall conformation had been deduced, questions remained. The idealized WC-model could not explain certain sequence-specific effects; an atomic picture was lacking.

In 1980 Dickerson and coworkers were the first to solve the crystal structure of a DNA duplex [Wing et al., 1980]. They refined the WC-model and showed that the ideal helical parameters (as theoretically predicted by Watson and Crick) are true on average but can deviate substantially dependent on sequence [Dickerson and Drew, 1981b,a, Drew et al., 1981]. Subsequently, more crystal structures of DNA sequences were solved, revealing large variations in helical parameters for B-DNA [Dickerson et al., 1982, Kopka et al., 1983, Heinemann and Alings, 1989] and giving structural insights into other conformations like A-DNA [Shakke et al., 1981, Conner et al., 1982, 1984] or Z-DNA [Drew et al., 1980, Wang et al., 1981, Drew and Dickerson, 1981, Rich et al., 1984]. A detailed atomic picture of DNA helical structure was now provided.

However it was found that crystallization can have profound effects on the conformation of DNA. In the crystalline state DNA strongly favours the A-form double helix, whereas DNA in solution occurs predominantly in the B-DNA form [Bloomfield et al., 2000]. Furthermore, the helical parameters strongly depend on the crystallization conditions [Jain and Sundaralingam, 1989, Shakke et al., 1989, Johansson et al., 2000]. Thus single crystal X-ray crystallography is of limited use when studying biological problems,

## 1 Introduction

particularly those involving DNA.

Parallel to the breakthrough of Dickerson and coworkers [Wing et al., 1980] the advent of 2-dimensional techniques [Jeener et al., 1979, Kumar et al., 1980a, Macura and Ernst, 1980] extended Nuclear Magnetic Resonance Spectroscopy (NMR) methods in a way that studying large biological molecules was now feasible. First efforts centered on protein structure determination [Wagner et al., 1981, Wuthrich et al., 1982, Zuiderweg et al., 1983], but eventually application to DNA structure determination in solution followed [Hare et al., 1983, Feigon et al., 1984, Clore and Gronenborn, 1984, 1985, Hosur et al., 1986]. These early studies focused on the sequential assignment of DNA or protein resonances, the structural content however was discussed only qualitatively. With the advent of powerful computers, techniques were developed that allowed for determination of 3-dimensional structures of biomolecules with NMR structural information as restraints [Williamson et al., 1985, Zuiderweg et al., 1985].

The development and subsequent refinement of the solid-phase phosphor-amidite approach for oligonucleotide synthesis [Sinha et al., 1984, Dahl et al., 1987, Schulhof et al., 1987, Caruthers et al., 1987] allowed for relatively cheap and easy access to large quantities of nucleic acids with a defined primary sequence. This marked a breakthrough for nucleic acids research since it was now possible to vary specific base positions in a predefined sequence. Thereby studying the effect of base mismatches on the helical arrangement of the duplex was facilitated [Kalnik et al., 1988, Roongta et al., 1990, Moe and Russu, 1992]. Furthermore, a means for introduction of arbitrary artificial nucleotides at any position in the duplex was provided by automated solid-phase synthesis.

Artificial DNA double strand structures have been investigated since the late 1980s [Li et al., 1987, Evans and Levine, 1988]. Several different types of modifications have to be distinguished. These involve: backbone modification [Pieters et al., 1989, Betts et al., 1995, Nielsen et al., 2009], fluorophores covalently linked to natural bases [Krugh et al., 1989, Schwartz et al., 1997, Subramaniam et al., 2001], fluorophores substituting a natural base [Nordlund et al., 1989, Guckian et al., 1998, Engman et al., 2004] or even a base pair [Matray and Kool, 1998, Guckian et al., 2000, Smirnov et al., 2002],

and intercalators, which bind to DNA through stacking and/or electrostatic interactions [Fede et al., 1993, Spielmann et al., 1995, Davies et al., 1997]. All of the latter studies focus on the introduction of chromophores, since their fluorescent properties can be exploited for studying DNA [Wojczewski et al., 1999].

The spectroscopic properties of covalently attached DNA modifications are utilized in numerous ways. Over the past decades different strategies have been developed for detecting single nucleotide polymorphisms (SNPs). These strategies employ fluorophore-quencher systems (molecular beacons) [Tan et al., 2004], DNA-mediated electron transfer (DETEQ) [Wagenknecht, 2008] or forced intercalation probes (FIT) [Koehler et al., 2005]. Furthermore, fluorescent molecules are introduced at different locations into DNA in order to get long-range structural information by exploiting fluorescence resonance energy transfer (FRET) [Lilley and Wilson, 2000]. In addition it has been demonstrated that transient absorption spectroscopy of fluorophore-modified DNA can be used to follow dynamics on the pico- to femtosecond timescale [Zewail, 2000].

Supramolecular vibrational modes of biological molecules are important for their function, and many have frequencies below  $200\text{ cm}^{-1}$  or  $6\text{ THz}$ . Examples are the primary event of vision ( $60\text{ cm}^{-1}$ ) [Wang et al., 1994], oxygen acceptance of hemoglobin ( $39\text{ cm}^{-1}$ ) [Klug et al., 2002], chemical reactions in myoglobin ( $51\text{ cm}^{-1}$ ) [Austin et al., 1989], and conformational change of bacteriorhodopsin ( $115\text{ cm}^{-1}$ ) [Xie et al., 2001]. For DNA transcription the double helix must be opened to expose the coding bases to chemical reactions. Thermal melting of double-stranded oligonucleotides is similar because it starts with a “denaturation bubble” [Prohofsky et al., 1979]. The latter is reached through collective modes between  $60$  and  $140\text{ cm}^{-1}$  which compress and stretch the interbase H-bonds [Cocco and Monasson, 2000]. However, such resonances in the low-frequency region are difficult to detect due to mixing of the DNA modes with those of hydration water. Resolving such collective vibrational modes of a biological molecule by molecular THz spectroscopy is a new but potent application for chromophores in DNA.

Here the chromophore functions like a THz light source when its charge distribution is suddenly altered by femtosecond optical excitation  $S_1 \leftarrow S_0$ . The electric field around

## 1 Introduction

the probe is changed instantly and acts on nearby groups with partial charges. Most of these change their nuclear position in an overdamped fashion but some may oscillate briefly. Altogether a reaction field  $R(t)$  is created which is reported by the polar probe molecule, through an emission frequency which depends on  $R(t)$ . The probe molecule is therefore not only light source but also detector. A response function can be obtained which is related to the local THz absorption spectrum. In this way the low-frequency vibrational structure of biomolecules can be accessed.

Molecular THz spectroscopy should reduce inhomogeneous broadening because the perturbing electric field and the reaction field are local. Only those modes will interact which have oscillator strength in the region, at the right direction. The obvious disadvantage is the need to embed a probe molecule inside double-stranded DNA as an artificial nucleobase. The probe has to be free of internal modes which are active below  $\approx 300\text{ cm}^{-1}$ , since they would mix with the macromolecular dynamics to be reported. For this reason the best-studied polarity probes, coumarins [Horng et al., 1995, Zhao et al., 2005], are not eligible. Instead one must use chromophors which have been shown to report the far infrared spectrum of pure liquids such as acetonitrile [Ruthmann et al., 1998, Karunakaran et al., 2008] or water [Lustres et al., 2005]. Required is bio-organic development of suited chromophores guided by optical femtosecond spectroscopy in the condensed phase. However, excellent suitability from an optical point of view is to no avail when the helical structure is severely disrupted, since duplex features are to be probed.

Thus, for all aforementioned spectroscopic techniques which investigate DNA features, it is advantageous or even imperative to know the exact orientation of the fluorophore inside the DNA double helix. Moreover it is instructive to have information on the stacking interactions of the fluorophore with the adjacent base pairs. Finally, it can be decisive - especially for biologically motivated hybridization studies - to be able to characterize the structural and dynamic perturbation of the DNA helical structure in terms of helical parameters and base pair lifetimes.

In order to solve above question, this work utilizes NMR spectroscopy for the structure

**Fig. 1.1:** DNA duplex sequence with chemical structure of the 2AP-T and A-T base pairs. A symmetric, nonpalindromic 13 base pair sequence was chosen to dismiss the possibility of mispairing, loop formation or fraying effects and to have a single perturbation site.

**Fig. 1.2:** DNA duplex sequence with chemical structure of the HNF fluorophore. Opposite to the HNF residue has been placed an abasic site (Y) in order to minimize steric strain on the HNF residue.

determination of the DNA sequences given in Fig. 1.1 and 1.2 in order to solve above question. In both sequences the central base or base pair is modified in order to have the single modification site and its adjacent base pairs unperturbed by fraying effects at the helix termini [Nonin et al., 1995]. Two different modifications are examined, 2-Aminopurine (2AP) and 2-Hydroxy-7-nitrofluorene (HNF).

#### *Duplex DNA with 2-Hydroxy-7-nitrofluorene*

The probe HNF is incorporated opposite to an abasic site (1'-2'-dideoxyribose) to avoid steric strain which might otherwise disrupt the overall B-DNA conformation or force the fluorophore into an extrahelical position. However, deletion of the partner base introduces increased flexibility into the DNA duplex at the modification site [Lin and de los Santos, 2001, Smirnov et al., 2002]. In conjunction with the different electronic properties of the HNF residue as compared to a natural base pair, HNF is expected to introduce large local perturbations compared to a more native modification. A first purpose of this work is to find out whether the DNA duplex adopts an overall B-DNA conformation

## 1 Introduction

with the HNF stacked inside the double helix. This information is essential since HNF has been designed to report on macromolecular vibrational modes in DNA via transient absorption spectroscopy, which cannot be observed in case of an extrahelical orientation of HNF.

### *Duplex DNA with 2-Aminopurine*

The 2AP-containing duplex represents a substantially different case. 2AP causes only a slight perturbation of the directly adjacent base pairs as suggested in earlier works by Lycksell et al. [1987] and Nordlund et al. [1989]. 2AP is commonly used to monitor base stacking-unstacking events in biologically relevant sequences [Allan and Reich, 1996, Reddy and Rao, 2000, Bernards et al., 2002, Daujotyte et al., 2004, Neely et al., 2005, Lenz et al., 2007]. Therefore it is crucial to characterize the perturbation induced upon 2AP incorporation structurally (in terms of helical parameters) and dynamically (in terms of reliable base pair lifetimes). This is the second aim of this work.

Since 2AP is structurally isomeric to adenine (A), it closely resembles the latter in size and shape. It has been found that it can also form stable base pairs with thymine (T) [Ronen, 1979, Sowers et al., 1986]. The two duplex structures of 13merRef with X=A and 13mer2AP with X=2AP differ only in the location of the amino group of the central residue (see Fig. 1.1). Thus any structural or dynamic differences that are observed between the two corresponding solution structures can be directly attributed to the incorporation of 2AP. This is the major difference compared to pertinent works; these investigate a ten base pair palindromic DNA duplex with two 2AP residues incorporated [Lycksell et al., 1987, Nordlund et al., 1989].

## 2 Theoretical background

### 2.1 Structural aspects of DNA

DNA is composed of four naturally occurring nucleobases, adenine (A), guanine (G), thymine (T) and cytosine (C). While A and G are derived from purine, T and C are pyrimidine derivatives. Base pairs are formed between A:T and G:C. The structure and nomenclature of these two base pair motifs is depicted in Fig. 2.1. The higher thermodynamic stability of G:C compared to A:T base pairs [Xia et al., 1998] originates from the fact that the latter base pair forms only two instead of three hydrogen bonds (Fig. 2.1).

By attaching A, G, C, or T to the C1'-atom of a 2''-deoxy- $\beta$ -D-ribose the nucleosides adenosine, guanosine, cytidine and thymidine are formed, respectively. The structure and nomenclature of 2''-deoxy- $\beta$ -D-ribose, which is called sugar in the following, is shown in Fig. 2.2. All atoms of the sugar are marked with a “ ’ ” to distinguish them from nucleobase atoms. The sugar conformation is defined by five dihedral angles  $\nu_0 - \nu_4$  (Fig. 2.3). The latter are interdependent and thus can be described by only two parameters

$$\nu_j = \Psi_m * \cos(P + 144(j - 2)) \quad j = 0, 1, 2, 3, 4 \quad (2.1)$$

the pucker angle  $P$  and the pucker amplitude  $\Psi_m$ . Note that this simple relation is valid only for cyclopentane, but deviations can be accounted for by introducing correction terms [Altona and Sundaralingam, 1972].

The glycosidic torsion angle  $\chi$  and the backbone dihedral angles  $\alpha - \zeta$  can be used to characterize the helical structure of DNA (Fig. 2.3). While  $\alpha - \zeta$  define the sugar-

## 2 Theoretical background

phosphate backbone of DNA,  $\chi$  determines the position of the nucleobase relative to the sugar. Two different orientations are sampled, the anti range which centers around  $\chi = -135^\circ$  and the syn range which samples values around  $\chi = +45^\circ$  [Bloomfield et al., 2000]. The latter is less stable as the nucleobase is located above the sugar, which leads to steric clashes. Thus the syn-orientation of nucleobases is only found for a special helical arrangement of DNA, the left-handed Z-DNA, which needs external stabilization, e.g. by high salt concentration [Rich et al., 1984].

Two main helical arrangements are found for DNA, the A-form and the B-form. While the former is more often found in crystal structures, B-DNA is the dominant conforma-

tion in solution. The most important parameters for both helical arrangements are compiled in Fig. 2.4. While the overall arrangement is similar (right-handedness, glycosidic bond orientation), differences exist. One that is commonly used to distinguish between the two helical arrangements is the sugar conformation, with C3'-endo (P around  $18^{\circ}$ ) dominant for A-DNA and C2'-endo (P around  $162^{\circ}$ ) for B-DNA. The widths of the minor and major grooves, which are depicted on the molecular and atomic level in Fig. 2.1 and Fig. 2.4 respectively, also differ significantly. The larger helical rise and twist va-

## 2 Theoretical background

**Fig. 2.5:** Helical parameters that describe the orientation of base pairs relative to the molecular frame (upper row), base pair partners (middle row) and consecutive base pairs (lower row) relative to each other. The picture is taken from Roberts [1993].

values for B-DNA lead to an elongated shape of the latter, while A-DNA is much more compressed (Fig. 2.4).

The helical parameters, which are visualized in Fig. 2.5, describe the arrangement of oligonucleotides in a double helix. They can be divided into three subgroups. Parameters in the upper row yield information on the orientation of base pairs relative to the molecular frame. The middle row parameters report on the orientation of the two base pair partners relative to each other. The lower row is most often used to characterize the helical arrangement, since these parameters give information about the orientation of two consecutive base pairs relative to each other. Especially the rise and twist-values determine the overall shape of the double helix (Fig. 2.4).

## 2.2 Base pair dynamics in DNA

### 2.2.1 Imino proton exchange theory

The imino protons of G and T are located near the helical axis at the center of each base pair and thus are effectively shielded against solvent or catalyst attack. Consequently, the central assumption in imino proton exchange theory of DNA is that exchange with bulk water can only proceed via a transient opening of the base pair [Kochoyan et al., 1987, 1988, Leijon and Graslund, 1992]. For Watson-Crick duplexes, base pair lifetimes do not depend on the nature of the adjacent pairs. This suggests that opening involves single base pairs only; the possibility of collective opening motions is ruled out [Leroy et al., 1985, Gueron et al., 1987].

Fig. 2.6 depicts a kinetic scheme of the processes involved in imino proton exchange theory [Leijon and Graslund, 1992]. Exchange from the closed state is not possible [Nonin et al., 1995], thus the first step must be the opening of the base pair with rate constants  $k_{op}$  and  $k_{cl}$  for opening and closing, respectively. From the open state, where the imino proton is assumed to be fully accessible [Kochoyan et al., 1988], two different processes can occur: exchange via an external base catalyst (rate constant  $k_{cat}^{ext}$ ) and via an intrinsic pathway ( $k_{cat}^{int}$ ). As a possible intrinsic catalyst the endocyclic nitrogen of the complementary base has been proposed [Leroy et al., 1985, Kochoyan et al., 1988]. Frequently used external base catalysts are Trishydroxymethylaminomethane (TRIS) or ammonia [Kochoyan et al., 1988, Moe and Russu, 1990, Bhattacharya et al., 2002].

Under conditions of a stable structure ( $k_{op} \ll k_{cl}$ ), which can be safely assumed for duplex lengths  $> 10$  base pairs, the concentration of base pairs in the open state  $[NH^*]$  is quasistationary, i.e. the kinetics are pseudo-first-order.

$$\frac{d[NH^*]}{dt} = 0 = k_{op} [NH^* \cdots N] - (k_{cl} + k_{cat}^{int} + k_{cat}^{ext}) [NH^*] \quad (2.2a)$$

$$(k_{cl} + k_{cat}^{int} + k_{cat}^{ext}) [NH^*] = k_{op} [NH^* \cdots N] \quad (2.2b)$$

$$[NH^*] = \frac{k_{op}}{(k_{cl} + k_{cat}^{int} + k_{cat}^{ext})} [NH^* \cdots N] \quad (2.2c)$$

## 2 Theoretical background

**Fig. 2.6:** Kinetic scheme of imino proton exchange

The effective imino proton exchange rate  $k_{ex}$  is defined by

$$k_{ex}[NH^* \cdots N] = (k_{cat}^{int} + k_{cat}^{ext})[NH^*] \quad (2.3)$$

where  $[NH^* \cdots N]$  is the concentration of the base pair in the closed state. Substituting eq. (2.2c) into eq. (2.3) and cancelling of  $[NH^* \cdots N]$  gives

$$k_{ex} = k_{op} \frac{k_{cat}^{int} + k_{cat}^{ext}}{k_{cl} + k_{cat}^{int} + k_{cat}^{ext}} \quad (2.4a)$$

$$\frac{1}{k_{ex}} = \frac{1}{k_{op}} \left( 1 + \frac{k_{cl}}{k_{cat}^{int} + k_{cat}^{ext}} \right) \quad (2.4b)$$

which can be reduced to

$$\frac{1}{k_{ex}} = \frac{1}{k_{op}} + \frac{1}{K_{diss} (k_{cat}^{int} + k_{cat}^{ext})} \quad (2.5)$$

by substituting  $K_{diss} = \frac{k_{op}}{k_{cl}}$ . Introducing  $\tau_{ex} = \frac{1}{k_{ex}}$ , the imino proton exchange time, and  $\tau_{op} = \frac{1}{k_{op}}$ , the base pair lifetime, gives

$$\tau_{ex} = \tau_{op} + \frac{1}{k_{cat}^{int} K_{diss} + k_{cat}^{ext} K_{diss}} \quad (2.6)$$

The transfer rate of the imino proton to an external catalyst in the isolated mono-

nucleoside ( $k_i$ ) should be comparable to  $k_{cat}^{ext}$ . The former is given by

$$k_i = \frac{k_{coll} [B]}{1 + 10^{pK_a^n - pK_a^c}} = k_{iso} [B] \quad (2.7)$$

where  $k_{coll}$  is the collision rate constant and  $pK_a^n$  and  $pK_a^c$  are the  $pK_a$ -values for the nucleotide and the catalyst respectively [Eigen, 1964]. Since the latter are all constant, they can be substituted by introducing  $k_{iso}$ , the constant of proportionality between  $k_i$  and the concentration of the external base catalyst  $[B]$ . Thus  $k_{cat}^{ext}$  can be expressed as

$$k_{cat}^{ext} = \alpha k_{iso} [B] \quad (2.8)$$

where restricted accessibility of the imino proton in the open state as compared to the isolated nucleoside is taken into account by the parameter  $\alpha$ , which ranges from 0 (not accessible) to 1 (unrestricted accessibility). For natural base pairs and all the commonly used base catalysts  $\alpha$  was found to be approximately 1 [Kochoyan et al., 1988]. Consequently, differences in accessibility might become important for modified nucleotides, but can be safely neglected for natural ones. Substituting eq. (2.8) into eq. (2.6) gives

$$\tau_{ex} = \tau_{op} + \frac{1}{k_{cat}^{int} K_{diss} + \alpha k_{iso} K_{diss} [B]} \quad (2.9)$$

which is an accurate description when  $k_{cat}^{int} \approx k_{cat}^{ext}$ . At high external base catalyst concentrations,  $k_{cat}^{ext}$  dominates  $k_{cat}^{int}$  and eq. (2.9) simplifies to

$$\tau_{ex} = \tau_{op} + \frac{1}{(\alpha k_{iso} K_{diss})} \frac{1}{[B]} \quad (2.10)$$

and the imino proton exchange time becomes a linear function of the inverse of the external catalyst concentration. In the other extreme case, when no external catalyst is available,  $k_{cat}^{int} \gg k_{cat}^{ext}$  and consequently eq. (2.9) reduces to

$$\tau_{ex} = \tau_{op} + \frac{1}{k_{cat}^{int} K_{diss}} \quad (2.11)$$

## 2 Theoretical background

which means that changes in the imino proton exchange can be either due to different base pair lifetimes (which can be determined via eq. (2.10)) or altered intrinsic exchange.

Early works on imino proton exchange considered the opening of the base pair to be rate-limiting, i.e.  $k_{cl} \ll (k_{cat}^{int} + k_{cat}^{ext})$  [Teitelbaum and Englander, 1975b,a, Patel and Hilbers, 1975, Hilbers and Patel, 1975]. In that case, eq. (2.4a) simplifies to

$$k_{op} \frac{k_{cat}^{int} + k_{cat}^{ext}}{k_{cat}^{int} + k_{cat}^{ext}} = k_{op} = k_{ex} \quad (2.12)$$

which implies that imino proton exchange with water directly measures the lifetime of the closed base pair ( $\tau_{op}$ ) since the latter is no longer a function of  $[B]$ . Exchange occurs every time the base pair opens, thus  $\tau_{ex}$  and consequently  $\tau_{op}$  are maximal. As a result, base pair lifetimes published before 1985 were overestimated by approximately one order of magnitude. In that year Gueron and coworkers showed that  $\tau_{ex}$  depends on the external catalyst concentration [Leroy et al., 1985, Gueron et al., 1987], demonstrating that imino proton exchange in polynucleotides is not opening-limited. Instead, eq. (2.10) is validated by their results. By introducing the apparent dissociation constant  $\alpha K_d$  (eq. (2.13a)) [Kochoyan et al., 1988] one obtains the commonly used expression for  $\tau_{ex}$  (eq. (2.13b)):

$$\alpha K_d = \alpha k_{iso} K_{diss} \quad (2.13a)$$

$$\tau_{ex} = \tau_{op} + \frac{1}{(\alpha K_d)} \frac{1}{[B]} \quad (2.13b)$$

A plot of  $[B]^{-1}$  vs  $\tau_{ex}$  allows for determination of the apparent dissociation constant from the slope of the linear fit. However, interpretation of  $\alpha K_d$  is not straightforward and hampered by the approximations detailed above. Much more informative of base pair dynamics is  $\tau_{op}$ , which can be determined from the intercept with the ordinate (in the limit of infinite  $[B]$ ) of the plot  $[B]^{-1}$  vs  $\tau_{ex}$ .

Based on the reaction  $[BH^+] + [H_2O] \rightleftharpoons [B] + [H_3O^+]$  and the definition of the acidity constant ( $K_s$ )

$$K_s = K_{eq} [H_2O] = \frac{[B] [H_3O^+]}{[BH^+]} \quad (2.14)$$

an expression is obtained, which relates the concentration of free external base catalyst  $[B]$  and the total added base concentration  $[B_0]$ .

$$\frac{1}{[B]} = (1 + 10^{(pK_a^c - pH)}) \frac{1}{[B_0]} \quad (2.15)$$

It follows that  $[B]$  is a function of  $[B_0]$  and the pH-value.

The imino proton exchange time  $\tau_{ex}$  can be determined by measuring the line broadening of the imino proton resonance due to addition of base catalyst [Lycksell et al., 1987].

$$\frac{1}{\tau_{ex}} = \pi \Delta \quad (2.16)$$

Line broadening provides an easy and time-efficient way to experimentally determine  $\tau_{ex}$ . However, since line broadening can also have other sources apart from the exchange process (e.g. different shim settings for each titration point) results obtained with this method tend to be inaccurate.

An alternative way is to calculate  $\tau_{ex}$  from the difference of the spin-lattice relaxation time with ( $T_1^{ext}$ ) and without external base catalyst ( $T_1^{int}$ ) [Bhattacharya et al., 2002].

$$\frac{1}{\tau_{ex}} = \frac{1}{T_1^{ext}} - \frac{1}{T_1^{int}} \quad (2.17)$$

$T_1^{ext}$  and  $T_1^{int}$  can be measured by NMR spectroscopy with high precision - errors below 2 % can be achieved [Sass and Ziessow, 1977] - and thus allow for more precise values of  $\tau_{ex}$  to be determined.

### 2.2.2 Inversion recovery experiments

Base pair dynamics of DNA can be followed by NMR spectroscopy. As detailed above (section 2.2.1), the key observable is chemical exchange of imino protons with bulk water as a function of external catalyst concentration. According to eq. (2.17)  $\tau_{ex}$  can be measured by determining  $T_1^{ext}$  and  $T_1^{int}$ . However, a difference in magnetization between the imino proton and water protons has to be created in order to make the exchange observable by NMR.

This difference can be created by employing two alternative experimental approaches, each of which targets either the water or the imino proton signals. Consequently, four different approaches can be distinguished in the literature: *selective saturation of the water signal* [Leroy et al., 1985, Nonin et al., 1995], *selective saturation of the imino proton region* [Lycksell et al., 1987, Kochoyan et al., 1987, 1988, Leroy et al., 1988, Moe and Russu, 1990, 1992, Leijon and Graslund, 1992, Leroy et al., 1993, Folta-Stogniew and Russu, 1994, Moe et al., 1995, Folta-Stogniew and Russu, 1996, Leijon, 1996], *selective inversion of the water signal* [Snoussi and Leroy, 2001, Mihailescu and Russu, 2001, Chen and Russu, 2004, Coman and Russu, 2005] and *selective inversion of the imino proton region* [Dornberger et al., 1999, Bhattacharya et al., 2002].

Although the majority of the former studies used the saturation recovery method, more recent works rely on inversion recovery experiments. Saturation recovery might be preferable for measurements of long  $T_1$ -values ( $> 5$  s) [Levy and Peat, 1975] or when the choice of optimal delay times is difficult due to a large range of  $T_1$ -values of interest [Roscher et al., 1996]. But these conditions are clearly not fulfilled for  $T_1$ -values of imino protons which are on a ms-timescale [Moe and Russu, 1990]. Becker et al. [1980] compared the efficiency of inversion and saturation recovery in determining  $T_1$ -values with a certain precision. They report inversion recovery to be much more efficient, with saturation recovery requiring 8-times more scans to achieve comparable signal-to-noise ratio [Weiss et al., 1980, Becker et al., 1980]. Thus inversion recovery should generally be preferred over saturation recovery experiments.

As to the question whether to invert the water or the imino proton region, no com-

prehensive study has yet been made. Regarding water inversion, Mihailescu and Russu [2001] point out that in order to obtain values for  $\tau_{ex}$ , the magnetization of the imino protons as a function of the exchange delay  $\tau$  has to be fitted to the equation

$$M(\tau) = M(0) - \frac{[M(0) - M^0]}{(T_1 + k_{ex})^{-1}} - \frac{k_{ex} M_0 T_1^{water} \tau}{(q - 1)^{-1}} \quad (2.18)$$

where the values of  $T_1^{water}$  and  $q$  (efficiency of inversion for the water signal) have to be determined in a separate experiment. Furthermore, the value of  $(T_1 + k_{ex})$  is determined for each imino proton resonance of interest by selective saturation [Mihailescu and Russu, 2001]. These additional experiments are time-consuming and thus inversion of the water signal is not to be preferred. In consequence, the method of choice for measuring base pair lifetimes is selective inversion of the imino proton region.

In the standard inversion recovery experiment the z-magnetization of one or multiple spins is inverted by an initial  $180^\circ$ -pulse ( $+M_z \rightarrow -M_z$ ). After a variable delay time ( $\tau$ ) a  $90^\circ$ -pulse is used to detect the recovered magnetization (Fig. 2.7). The plot of signal intensity vs delay time is fitted exponentially with three instead of two parameters ( $A, B$  and  $T_1$ ) to account for imperfect inversion of the signal

$$I(\tau) = A + B \exp(-\tau/T_1) \quad (2.19)$$

[Sass and Ziessow, 1977, Kowalewski et al., 1977]. To create differences in magnetization between water and the imino protons, the initial  $180^\circ$ -pulse has to be applied selectively to the imino proton region.

Selective inversion can be achieved in numerous ways. In principle, the commonly used constant-amplitude (rectangular), unselective (hard) pulse can be applied selectively by varying the pulse length and adjusting the pulse power. Rectangular pulses have the advantage of relatively straightforward implementation and optimization due to their analytical solution to the Bloch equations [Hajduk et al., 1993]. However, the excitation profile, which can be calculated by the latter equations, is imperfect. While there is a central lobe of strong excitation, the sharp leading and trailing edges of the pulse give rise

## 2 Theoretical background

to a set of sidelobes (cf. Fig. 2.8), whose amplitude decreases with offset from the centre frequency [Freeman, 1992]. The sidelobes lead to considerable off-resonance excitation. Similar reasoning can be applied to inversion. In order to reduce off-resonance excitation, the transition region at the edges of the pulse must be smoothed.

A number of shaped pulses for selective bandwidth inversion were created when - with the advent of the computer - numerical calculation of the Bloch equations became possible. Among the first shapes to be proposed was the Gaussian pulse envelope, which is still popular [Bhattacharya et al., 2002]. The advantage of the latter is that in the linear response region (pulse length  $\tau_p \ll T_1, T_2$ ) the excitation

function is another Gaussian (see Fig. 2.8). Thus sidelobes are effectively avoided [Bauer et al., 1984]. However, a Gaussian excitation function is far from the ideal of a rectangle, consequently the completely inverted region is quite small [McDonald and Warren, 1991]. Other pulse shapes like Hermitian [Warren, 1984], Gaussian cascades [Emsley and Bodenhausen, 1990] and quaternion pulses [Emsley and Bodenhausen, 1992] try to extend the region of complete inversion with increasing success.

However, the advantages, which were outlined above are achieved at the cost of longer pulse durations. But when the the relaxation times  $T_1$  and  $T_2$  become comparable to (or even shorter than) the pulse duration, relaxation during the  $180^\circ$ -pulse is no longer negligible. This can have a profound effect on the excitation profile and hamper applicability of shaped pulses for selective excitation [Hajduk et al., 1993]. Furthermore, most shaped pulses were derived on the basis of the Bloch equations neglecting such effects as radiation damping, relaxation and coupling [McDonald and Warren, 1991]. While each of these effects can be accounted for separately [Warren et al., 1989, Hajduk et al., 1993, Ewing et al., 1990], to account for all of them at once is difficult.

The adiabatic sweep is a completely different approach to selective bandwidth inversion. The usually employed pulsed NMR experiment is operated at a static magnetic field  $B_0$  and uses a pulsed magnetic field  $B_1$  to simultaneously invert all frequencies of

**Fig. 2.7:** Scheme of a general inversion recovery pulse sequence

**Fig. 2.8:** Pulse shapes and excitation forms of a) rectangular and b) Gaussian pulse. This picture is taken from McDonald and Warren [1991].

interest with a constant, bandwidth-centered carrier frequency. In the adiabatic passage experiment, the carrier frequency is modulated over the whole bandwidth and thus the frequencies of interest are inverted successively [Tannús and Garwood, 1997]. An alternative, equivalent approach is to modulate the phase of the center frequency [Garwood and DelaBarre, 2001]. Adiabatic pulses have two main advantages over standard pulses. They are rather insensitive to  $B_1$  field inhomogeneity [Bohlen and Bodenhausen, 1993] and require much less radiofrequency power for inverting nuclear spins over a wide range of chemical shifts [Kupce and Freeman, 1995]. Many different pulse shapes, which enhance one or the other advantage, were created: the hyperbolic secant pulse [Silver et al., 1984, 1985], the chirped pulse [Bohlen and Bodenhausen, 1993, Fu and Bodenhausen, 1995] or the WURST pulse [Kupce and Freeman, 1995, 1997]. Some are now utilized in broadband heteronuclear spin decoupling where radiofrequency power is limited [Kupce and Freeman, 2007] or in *in vivo* NMR where surface coils with a spatially inhomoge-

## 2 Theoretical background

neous  $B_1$  field are used [Tannús and Garwood, 1997]. Yet there are also disadvantages. One of them is a distinct phase distortion which is introduced for large bandwidths due to the different times at which the frequencies are inverted. This disadvantage can be circumvented, however, by introducing a second adiabatic pulse which cancels the phase distortion introduced by the first [Kupce and Freeman, 1997]. Further disadvantages are the requirement that adiabatic rotations must be accomplished rapidly relative to  $T_1$  and  $T_2$  of the nuclear spins of interest [Garwood and DelaBarre, 2001]. This limits application of adiabatic pulses to spins with quite long relaxation times and those which span a large number of chemical shifts, e.g. heteronuclei like  $^{13}\text{C}$ .

## 2.3 Solution structure determination of DNA

### 2.3.1 Nuclear Overhauser Effect spectroscopy

NMR spectroscopy has become the method of choice for structure determination of biomolecules in solution. This success is primarily based on the possibility to directly extract distance information utilizing the Nuclear Overhauser Enhancement effect (NOE). Overhauser [1953] was the first to discover that the intensity of the signal of one resonance is changed upon perturbation of another due to cross-relaxation. Initially the NOE was observed by selective saturation of one line and subsequent recording of the 1D spectrum over the whole spectral region of interest. This approach proved to be very useful for the structure elucidation of small molecules [Colson et al., 1967, Woods et al., 1968, Schirmer et al., 1970, Schirmer and Noggle, 1972]. Its applicability to biomolecules however, was limited by the long accumulation time and severe spectral overlap which leads to poor selectivity of saturation [Kumar et al., 1981]. The development of the 2D-NMR spectroscopy finally allowed to acquire the complete set of NOE effects for a macromolecule with a single experiment [Macura and Ernst, 1980]. Furthermore, the 2D Nuclear Overhauser Enhancement Spectroscopy (NOESY)-experiment could be readily repeated in  $H_2O$  [Kumar et al., 1980b].

The pulse sequence of a general 2D NOESY experiment is shown in Fig. 2.9. With an initial  $90^\circ$ -pulse transverse magnetization is created. The latter is allowed to precess freely during the evolution time  $t_1$ , thereby frequency-labelling the magnetization components. A second  $90^\circ$ -pulse rotates the magnetization onto the negative z-axis.

During the subsequent mixing period with variable length  $\tau_m$ , z-magnetization components exchange through dipole-dipole cross-relaxation. A third  $90^\circ$ -pulse again creates transverse magnetization which is finally detected. All three pulses are applied non-selectively [Macura and Ernst, 1980].

In the absence of scalar spin-spin-interactions, cross-relaxation of the longitudinal

**Fig. 2.9:** Scheme of a general NOESY pulse sequence

**Fig. 2.10:** The cross-relaxation network of  $N$  groups of nuclei. The cross relaxation rates  $R_{ij}$  lead to a distribution of magnetization within the system, while the leakage relaxation rates  $R_i$  lead to a loss of magnetization towards the environment. This picture is taken from Macura and Ernst [1980].

magnetization components  $M_{ij}$  can be described with the equation:

$$\dot{\mathbf{m}} = \mathbf{R} \times \mathbf{m} \quad (2.20)$$

$\mathbf{R}$  is the relaxation matrix comprising the cross relaxation rates  $R_{ij}$  and the external relaxation (leakage) rates  $R_i$  (Fig. 2.10). The vector  $\mathbf{m}$  comprises the deviation of  $M_{zi}$  from thermal equilibrium for  $i$  spins

$$m_i = M_{zi} - \frac{n_i}{N} M_o \quad (2.21)$$

where  $M_o$  is the total equilibrium magnetization of the  $N$  nuclei. After the evolution period the initial z-magnetization components are encoded by the precession frequencies

of the components ( $\omega_i$ )

$$m_i(0) = M_o \frac{n_i}{N} \left[ \cos(\omega_i t_1) \exp \left( -\frac{t_1}{T_{2i}} \right) - 1 \right] \quad (2.22)$$

such that the cross-relaxation pathway can be traced back to its origin. The recovery of the magnetization back to equilibrium during the mixing period can be described by the following solution to eq. (2.20) [Macura and Ernst, 1980]

$$\mathbf{m}(\tau_m) = \exp[-\mathbf{R} \tau_m] \mathbf{m}(0) \quad (2.23)$$

where  $\mathbf{m}(\tau_m)$  is the matrix comprising the magnetization components after the mixing period,  $\mathbf{m}(0)$  represents the intensities of the diagonal peaks at  $\tau_m = 0$ . The diagonal ( $R_{ii}$ ) and off-diagonal ( $R_{ij}$ ) relaxation matrix elements are given as [Roberts, 1993]:

$$R_{ii} = q_{ij} \sum_{i,j} \left\{ J_{0,ij}(\omega_i - \omega_j) + 3 [J_{1,ij}(\omega_i) + J_{1,ij}(\omega_j)] + \right. \\ \left. 6 J_{2,ij}(\omega_i + \omega_j) + R_{1i} \right\} \quad (2.24a)$$

$$R_{ij} = q_{ij} [6 J_{2,ij}(\omega) - J_{0,ij}(\omega)] \quad (2.24b)$$

where  $R_{1i}$  is the leakage rate, which can usually be neglected in the absence of paramagnetic nuclei. The factor  $q_{ij}$  comprises all constant values

$$q_{ij} = \frac{\gamma_i^2 \gamma_j^2 \hbar^2 \mu_0^2}{160 \pi^2} \quad (2.25)$$

where  $\gamma_i$  and  $\gamma_j$  are the gyromagnetic ratios for spins i and j respectively,  $\hbar$  is the Planck constant (divided by  $2\pi$ ) and  $\mu_0$  is the magnetic constant or vacuum permeability.  $J_{n,ij}(\omega)$  represents the spectral densities for the zero, single and double quantum transitions (n=0,1,2 resp.)

$$J_{n,ij}(\omega) = \frac{\tau_c^{ij}}{1 + (n \omega_0 \tau_c^{ij})^2} \frac{1}{r_{ij}^6} \quad (2.26)$$

## 2 Theoretical background

where  $\tau_c^{ij}$  is the rotational correlation time of the vector between spins  $i$  and  $j$  and  $r_{ij}$  is the distance between the latter. Since the differences in resonance frequency for various spins are negligibly small compared to the value of the resonance frequency itself,  $\omega_i$  and  $\omega_j$  are approximated by the center frequency  $\omega_0$ . The factor  $n$  in the denominator is given by the number of quanta involved in the transition. With the help of some assumptions the intensities of NOE cross-peaks can be directly related to distances in the molecule under investigation, as is seen in the next section.

### 2.3.2 Structural information from Nuclear Overhauser Enhancement effects

The NOE effect is an invaluable tool for structure elucidation, since it is correlated with the distance between the interacting nuclei. There are different methods to extract structural information out of NOE cross-peak intensities. A very popular method is to classify peaks according to their peak intensities into strong, medium and weak and setting up loose distance restraints of 1.8-2.8 Å, 1.8-3.3 Å and 1.8-5.0 Å, respectively. This approach has the clear advantage of simplicity and abolishes the need to integrate NOE cross-peaks in the 2D-spectrum. However, intensities are only representative of peak volumes when the lineshape for all peaks is the same. This is true only when the digital resolution is larger than the peakwidth [Roberts, 1993], which is clearly not fulfilled for modern high-resolution spectra of macromolecules. A second disadvantage is that such loose distance restraints do not have much restraining power and consequently the structure is ill-defined. In particular for nucleic acids, the classification on the basis of peak intensities is unsuitable, since the proton density is much less than in proteins (0.35 protons/atom versus 0.52 protons/atom in proteins) and thus yields fewer distance restraints. Additionally, long-range peaks as detected in proteins cannot be observed in DNA due to its rod-like shape. The need for more accurate distance restraints in DNA structure determination by NMR is thus intensified [MacDonald and Lu, 2002].

Very accurate distance restraints can be extracted using the Full Matrix Relaxation Approach. Here distances are calculated directly from the off-diagonal elements of the relaxation matrix, which in turn is obtained via

$$\mathbf{R} = \frac{\ln[\mathbf{m}(0)] - \ln[\mathbf{m}(\tau_m)]}{\tau_m} \quad (2.27)$$

[Roberts, 1993]. To obtain the complete intensity matrix  $\mathbf{m}$  is not possible in practice. Thus two different algorithms have been proposed to fill the “gaps” in  $\mathbf{m}$ . Schematic representations for both algorithms are given in Fig. 2.11. Both algorithms rely on a reasonable starting structure from which an intensity matrix is calculated. The latter is then combined with the intensity matrix derived from the experimental NOEs and

## 10: Structure determination from NMR data I

**Fig. 2.11:** Two different approaches to obtain distances from NOE experiments. While one approach is based on the self-consistency of the relaxation matrix (right part), the other relies on external structure calculation (left part). Popular implementations of these approaches are the programs MARDIGRAS [Borgias and James, 1990] and IRMA [Boelens et al., 1988]. This picture is taken from Roberts [1993].

the relaxation matrix is calculated using eq. (2.27). At this step the two algorithms differ. One approach checks the relaxation matrix for self-consistency and produces a reconciled relaxation matrix (MARDIGRAS [Borgias and James, 1990]) from which the intensity matrix is in turn calculated. The other approach (IRMA [Boelens et al., 1988]) produces a set of distance restraints from the relaxation matrix. The restraints are used to refine the starting structure. The refined structure is then used to calculate an intensity matrix and the process starts all over again. The main advantage of either approach

is that by measuring NOESY spectra at different mixing times, spin diffusion can be accounted for and very accurate distance restraints are produced. However, as pointed out by Lane [1996] and Tonelli and James [1998] error limits are often too small since conformational averaging leads to considerable errors in NOE intensity. Furthermore, acquiring and especially accurately integrating NOE data for several mixing times is exceedingly time-consuming.

A third possibility to derive distance restraints from NOE cross-peak intensities is the Isolated Spin Pair Approximation (ISPA). Several assumptions are made. First, a single correlation time ( $\tau_c$ ) for the whole molecule is introduced, with which  $\tau_c^{ij}$  in eq. (2.26) is replaced.

$$J_{n,ij}(\omega) = \frac{\tau_c}{1 + n^2 \omega_0^2 \tau_c^2} \frac{1}{r_{ij}^6} \quad (2.28)$$

In some cases local mobility of residues must be taken into account and a modified spectral density function has to be used [Lipari and Szabo, 1982a,b]

$$J_{n,ij}(\omega) = \left( \frac{S^2 \tau_c}{1 + n \omega_0^2 \tau_c^2} + \frac{S^2 \tau_e}{1 + n \omega_0^2 \tau_e^2} \right) \frac{1}{2 r_{ij}^6} \quad (2.29)$$

where  $\tau_e$  is the effective correlation time of the local mobility site and  $S^2$  is the generalized order parameter, which is a measure for the flexibility of the site with values ranging from 0 (unrestricted motion) to 1 (fully restricted motion). In proteins, order parameters range from 1 to as low as 0.6 for flexible side chains [Flynn et al., 2001], while  $S^2$  in DNA is on the order of 0.8 for all proton pairs [Lane, 1993, 1996]. In the ISPA approach all distances are referenced to a fixed distance (both of which have  $S^2 \approx 0.8$ ). Thus the contribution of local mobility is cancelled. The assumption of a single correlation time for the whole molecule is valid since correlation times for base and sugar protons are comparable [Reid et al., 1989] and oligonucleotides shorter 15 base pairs in length can be assumed isotropic rotors [Birchall and Lane, 1990].

In the ISPA approach the matrix exponential of eq. (2.23) is approximated with a Taylor expansion

$$\exp[-\mathbf{R} \tau_m] = 1 - \mathbf{R} \tau_m + \frac{1}{2} \mathbf{R}^2 \tau_m^2 - \dots \quad (2.30)$$

## 2 Theoretical background

whereby the peak intensities in the NOESY spectrum are given as

$$A_{ij} = \delta_{ij} - R_{ij} \tau_m + \frac{1}{2} \sum_k R_{ik} R_{jk} \tau_m^2 - \dots \quad (2.31)$$

The central assumption in ISPA is that for short mixing times, the Taylor expansion can be truncated after the linear term. Thus any effects of spin diffusion, which is magnetization transfer over third atoms (represented by the quadratic term), are neglected and the cross-peak intensity ( $i \neq j$ ) becomes a linear function of  $r_{ij}^{-6}$ .

$$A_{ij} = R_{ij} \tau_m = q_{ij} \tau_c \tau_m \left( \frac{5 - 4 \omega_0^2 \tau_c^2}{1 + 4 \omega_0^2 \tau_c^2} \right) \frac{1}{r_{ij}^6} \quad (2.32)$$

Consequently, distances can be derived by referencing to a known, fixed distance whereby all constant terms are cancelled.

$$\frac{A_{ref}}{A_{ij}} = \left( \frac{r_{ij}}{r_{ref}} \right)^6 \quad or \quad r_{ij} = r_{ref} \sqrt[6]{\frac{A_{ref}}{A_{ij}}} \quad (2.33)$$

A commonly used reference distance is the C H5-H6 distance which is fixed at appr. 2.5 Å [Reid et al., 1989]. While many cross-peaks can be referenced with this distance, it is necessary to introduce several others to account for fast rotation in methyl groups (e.g. C7-H7) or solvent exchange with amino and imino protons (e.g. H42-H5).

**Fig. 2.12:** Panel (a) shows the steric interaction of DNA with Pf1 which prevents the DNA from tumbling isotropically and thus induces residual order. The latter gives rise to Residual Dipolar Couplings (RDC) which can be determined by measuring the difference in dipolar coupling of i.e. an N-H bond vector with and without alignment (panel (b)). This picture is taken from MacDonald and Lu [2002].

### 2.3.3 Residual Dipolar Couplings

In combination with NOE data, Residual Dipolar Couplings (RDC) are now routinely employed for the NMR structure determination of macromolecules as they compensate for the drawbacks of NOE data. Due to the  $r_{ij}^{-6}$ -dependence of the NOE (cf. section 2.3.1) only information on closely spaced spins ( $r_{ij} \approx 5 \text{ \AA}$ ) is provided. In proteins, long-range peaks between residues far apart in the primary sequence can be observed owing to the tertiary fold. Due to the rod-like shape of short and medium-size DNA, only information on directly adjacent base pairs is available. Long-range effects like kinking in A-tract DNA could thus not be described prior to the development of RDC measurement [MacDonald et al., 2001, Steff et al., 2004].

RDCs yield information on the orientation of bond vectors relative to the molecular frame. Thus also distant parts in a macromolecule can be characterized relative to each other, which significantly improves results from structure calculations, especially with regard to the global fold [Mauffret et al., 2002].

The first account of measuring anisotropic interactions was published more than 45

## 2 Theoretical background

years ago by Saupe and Englert [1963]. Only after the advent of high-resolution NMR spectrometers and methods, this technique could be applied to biological macromolecules with success. Bax and Tjandra [1997] were able to demonstrate that dissolving the protein ubiquitin in a very dilute solution of bicelles induces residual order while retaining the high resolution of NMR spectra. This marked a breakthrough in the field of biomolecular NMR since measurement of residual order effects such as RDCs, were not limited to molecules with natively high magnetic susceptibility anisotropy anymore [Tolman et al., 1995, Tjandra et al., 1996]. Initially application of RDCs to NMR structure determination centered on proteins [Bax and Tjandra, 1997, Tjandra and Bax, 1997, Tjandra et al., 1997], but subsequently the importance of RDCs for the structure determination of DNA was demonstrated extensively in theory [Vermeulen et al., 2000, Mauffret et al., 2002] and in practice [Tjandra et al., 2000, Zidek et al., 2001, MacDonald and Lu, 2002, Wu et al., 2004, Stefl et al., 2004].

Inducing just enough alignment for reliable measurement of RDCs, while retaining the high resolution and unambiguousness of the spectra is central to the success of RDC measurements. Tjandra and Bax [1997] showed that the degree of alignment can easily be adjusted by varying the concentration of the bicelles. In the following, diverse alignment media were developed in order to extend the applicability of the approach: bicelle-based alignment [Tjandra and Bax, 1997, Tjandra et al., 1997, Ottiger and Bax, 1999a, Barrientos et al., 2000, Al-Hashimi et al., 2000, Ruckert and Otting, 2000], filamentous phage [Hansen et al., 1998], stretched gels [Chou et al., 2001, Ma et al., 2008] or paramagnetic tagging [Wohnert et al., 2003]. The bacteriophage Pf1 proved to be particularly suited for aligning oligonucleotides since it is stable over a wide range of temperatures and Pf1-DNA interaction is minimized due to electrostatic repulsion between the two negatively charged macromolecules [Hansen et al., 1998, Prestegard et al., 2000]. The steric interaction of Pf1 with DNA is illustrated in Fig. 2.12 a.

RDCs ( $D_{ij}$ ) are determined by measuring the difference of the dipolar coupling in the

**Fig. 2.13:** Orientation of the magnetic field, defined by angles  $\xi_x, \xi_y, \xi_z$  and the internuclear vector, described by angles  $\zeta_x, \zeta_y, \zeta_z$ , in the macromolecular frame. This picture is taken from Blackledge [2005].

presence ( $^1J_{ij}^{ani}$ ) and absence of molecular alignment ( $^1J_{ij}^{iso}$ ), as is shown in Fig. 2.12 b.

$$^1J_{ij}^{ani} = ^1J_{ij}^{iso} + D_{ij} \quad (2.34)$$

The RDC term can be described by the following equation

$$D_{ij} = -\frac{\gamma_i \gamma_j \mu_0 \hbar}{4 \pi^2} \left\langle \frac{3 \cos^2 \alpha_{ij}(t) - 1}{2 r_{ij}^3(t)} \right\rangle \quad (2.35)$$

where  $\alpha$  denotes the angle of the internuclear vector between atoms  $i$  and  $j$  with the applied magnetic field and  $\langle \rangle$  designates the time and ensemble average. When no preferred alignment is induced, all values of  $\alpha$  are sampled with equal probability over time and thus  $D_{ij}$  is averaged to zero. If residual order is induced by aligning the molecule, information on the orientation of the internuclear vector can be extracted. However, in order to have a fixed reference system, it is desirable to relate the orientation of the internuclear vector to the macromolecular frame rather than the magnetic field. To achieve this, two conditions must be met: 1) the distance between the atoms which give rise to  $D_{ij}$  does not change significantly over time (or else its distribution is known), such that  $r_{ij}$  can be substituted in eq. (2.35) with an effective distance  $r_{ij}^{eff}$  which is known and where averaging is already taken into account. 2) It is assumed that for macromolecules the time average of  $\alpha$  can be expressed by two convoluted motions, the macromolecule tumbling with respect to the magnetic field vector ( $\xi_x, \xi_y, \xi_z$ ) and the internuclear vector

## 2 Theoretical background

moving inside the macromolecular frame  $(\zeta_x, \zeta_y, \zeta_z)$  as illustrated in Fig. 2.13.

$$\cos \alpha_{ij} = \begin{pmatrix} \cos \xi_x \\ \cos \xi_y \\ \cos \xi_z \end{pmatrix} \begin{pmatrix} \cos \zeta_x \\ \cos \zeta_y \\ \cos \zeta_z \end{pmatrix} = \sum_{k=x,y,z} \cos \xi_k \cos \zeta_k \quad (2.36)$$

To a first approximation, the internuclear vector is considered to be fixed within the macromolecular frame and thus time-averaging has no effect on  $\zeta$ . Introducing the alignment tensor  $\mathbf{A}$  with dimensionless units

$$A_{kl} = \langle \cos \xi_k \cos \xi_l \rangle \quad (2.37)$$

eq. (2.35) can then be rewritten as

$$D_{ij} = -\frac{3 \gamma_i \gamma_j \mu_0 \hbar S_{flex}}{8 \pi^2 (r_{ij}^{eff})^3} \sum_{k,l=x,y,z} \left( A_{kl} \cos \zeta_k \cos \zeta_l - \frac{1}{9} \delta_{kl} \right) \quad (2.38)$$

where  $S_{flex}$  represents an order parameter to account for local flexibility of the internuclear vector. Here the assumption is that the local motion does not influence the overall alignment of the macromolecule, which is reasonable in the absence of large amplitude fluctuations. In most cases, the local motion can be approximated with the diffusion-in-a-cone model, where the order parameter  $S_{flex}$  is related to the generalized order parameter  $S$ , which scales down the measured RDCs linearly [de Alba and Tjandra, 2002].

In the present framework the alignment tensor  $\mathbf{A}$  has all elements non-zero. It is however desirable to find a specific molecular frame in which all off-diagonal elements of  $\mathbf{A}$  are zero. Such a frame, called the principal axis system (PAS) can be found by a 3D Euler rotation of the current molecular frame with parameters  $\alpha, \beta$  and  $\gamma$  [Blackledge, 2005]. Eq. (2.38) can then be rewritten in terms of the polar angles  $\theta, \phi$  (Fig. 2.14, left panel), which describe the orientation of the internuclear vector in the eigenframe of the

**Fig. 2.14:** Orientation of the internuclear vector with polar coordinates  $\theta$  and  $\phi$  in the eigenframe of the alignment tensor with eigenvalues  $A_{xx}$ ,  $A_{yy}$  and  $A_{zz}$  (left panel). The right panel illustrates the orientational degeneracy of RDCs. As can be clearly seen a large number of different orientations can be sampled when the RDC takes intermediate values. Only extreme RDC value define unique orientations of the internuclear vector. This picture is taken from Blackledge [2005].

alignment tensor with eigenvalues  $|A_{xx}| \leq |A_{yy}| \leq |A_{zz}|$  [Lipsitz and Tjandra, 2004]

$$D_{ij} = -\frac{\gamma_i \gamma_j \mu_0 \hbar S_{flex}}{4 \pi^2 (r_{ij}^{eff})^3} [A_a (3 \cos^2 \theta - 1) + A_r \sin^2 \theta \cos 2\phi] \quad (2.39)$$

where  $A_a$  and  $A_r$  are the axial and rhombic components of the alignment tensor  $\mathbf{A}$  [Prestegard et al., 2000], which are given by

$$A_a = \frac{1}{2} A_{zz} \quad \text{and} \quad A_r = \frac{1}{2} (A_{xx} - A_{yy}) \quad (2.40)$$

In consequence, the alignment tensor  $\mathbf{A}$  is determined by 5 independent parameters: the three Euler angles needed for rotation of the reference frame  $(\alpha, \beta, \gamma)$  and the two components of the alignment tensor  $\mathbf{A}$  ( $A_a, A_r$ ). The alignment tensor can then be unambiguously determined from a minimum set of 5 experimental RDCs by singular value decomposition [Losonczi et al., 1999].

With  $\mathbf{A}$  at hand, the orientation of any internuclear vector with respect to the macro-molecular frame can be calculated. Unfortunately, there exists a multitude of orientations of an internuclear vector that is consistent with a given intermediate RDCs value, as is illustrated in Fig. 2.14, right panel. Only extreme values correspond to unambiguous

## *2 Theoretical background*

orientations. The orientational degeneracy for intermediate RDC values clearly limits their value for structure determination. Thus it is desirable to remove this degeneracy by either measuring more RDCs per residue, or RDCs for the same internuclear vectors but with a different alignment tensor [de Alba and Tjandra, 2002, Blackledge, 2005].

### 2.3.4 Simulated Annealing calculations

The main idea behind Simulated Annealing (SA) calculations is coupling simple energy minimization to Molecular Dynamics. Thus the problem that molecules converge to a local minimum instead of the global can be circumvented. The Newtonian equation of motion

$$F_i(t) = -\frac{\partial V}{\partial r_i} = m_i a_i(t) \quad (2.41)$$

relates the acceleration  $a_i(t)$  of each atom  $i$  at time  $t$  to the derivative of the potential energy ( $V$ ) with respect to the atom position  $r_i$ .  $F_i(t)$  represents the force which acts upon the atom  $i$  with mass  $m_i$  [Bloomfield et al., 2000]. The atoms are moved according to the force that is exerted upon them for a given time-step (typically between 1-5 fs). From the knowledge of the last and current atom positions and velocities, a new force is calculated which in turn acts on the atoms. This cycle is repeated until a convergence criterion (e.g. a minimum change in the gradient of the potential energy) is met. Initially, atom velocities are computed using a Gaussian or Maxwell distribution. The atom coordinates are derived from a starting structure. Since the initial coordinates and velocities determine all subsequent ones, it is important to start from a reasonable structure. This is usually achieved by starting from already known crystal or NMR structures.

Temperature-coupling of Molecular Dynamics is achieved by introducing an average kinetic energy which is computed via Boltzmann statistics

$$\langle E_{kin} \rangle = \langle \frac{1}{2} m \nu^2 \rangle = \frac{3}{2} k_b T \quad (2.42)$$

where  $k_b$  is the Boltzmann factor,  $m$  the atom mass and  $\nu$  the atom velocity. The higher the temperature ( $T$ ) is chosen, the higher the kinetic energy of the system. Thus at high temperatures kinetic barriers can be overcome, and the global minimum should be accessible.

The number of atoms in macromolecules such as DNA or proteins is on the order of thousands with three times as much cartesian coordinates to be calculated at each step. In order to make computation of macromolecules feasible, Molecular Dynamics calculati-

## 2 Theoretical background

ons rely on the predefinition of atom types. For these atom types many parameters such as bond lengths, bond angles, dihedral angles, partial charges etc. are assumed to be fixed and are comprised in the force field. In the present work the program XPLOD-NIH [Schwieters et al., 2003] was used, which employs the CHARMM force field [Weiner et al., 1984, MacKerell et al., 2000]. The total potential energy  $V_{tot}$  consists of two components [Brünger, 1996]

$$V_{tot} = E_{emp} + E_{eff} \quad (2.43)$$

where the empirical ( $E_{emp}$ ) and the effective energy term ( $E_{eff}$ ) are given as [Brünger, 1996].

$$E_{emp} = E_{bond} + E_{angle} + E_{dihe} + E_{vdW} + E_{Coulomb} \quad (2.44a)$$

$$E_{eff} = E_{noe} + E_{rdc} + E_{plan} + E_{cdih} \quad (2.44b)$$

$E_{bond}$ ,  $E_{angle}$ ,  $E_{dihe}$  and all energy terms of  $E_{eff}$  are calculated as the product of a scaling factor (the force constant) and the deviation of the observed value from the equilibrium one, e.g.

$$E_{bond} = k_{bond} (r_{ij}^{obs} - r_{ij}^{equ}) \quad (2.45)$$

The equilibrium values for  $E_{noe}$  and  $E_{rdc}$  are taken from experiment while these of  $E_{cdih}$  and  $E_{plan}$  are averages from the literature [Brünger, 1996]. The corresponding scaling factors are defined in the calculation input and thus can be used to increase the restraining power of selected energy terms. Equilibrium values and force constants of  $E_{bond}$ ,  $E_{angle}$ ,  $E_{dihe}$  constitute one part of the force field.  $E_{vdW}$  is given as

$$E_{vdW} = \sum_{i,j} \left( \frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^6} \right) \quad (2.46)$$

with  $A_{ij} = 2 \sqrt{\varepsilon_{ii} \varepsilon_{jj}} (\sigma_{ii} - \sigma_{jj})$  and  $B_{ij} = 2 \sqrt{\varepsilon_{ii} \varepsilon_{jj}} (\sigma_{ii} - \sigma_{jj})$ . The atomic permittivities ( $\varepsilon_{ii/jj}$ ) and van-der-Waals radii ( $r_{ii/jj}$ ) set up another part of the force field. The partial

### 2.3 Solution structure determination of DNA

atomic charges  $(q_i, q_j)$  in the  $E_{Coulomb}$ -term constitute the last part of the force field.

$$E_{Coulomb} = \sum_{ij} \frac{q_i q_j}{\varepsilon_0 r_{ij}} \quad (2.47)$$

When explicit treatment of water is not feasible due to restrictions on the calculation time, the solvent screening effect can be approximated by introducing a distance dependent permittivity of free space  $\varepsilon_0(r_{ij})$ .

Ultimately, force field parameters are based on crystal structures and ab-initio calculations of small model molecules (bond lengths, bond angles and dihedral angles), infrared spectroscopy data (force constants) and empirical testing (where no experimental source is available) [Weiner et al., 1984]. When chemically modified nucleotides are to be incorporated into calculations, parameters for this nucleotide have to be added to the existing force field. In the absence of experimental data, these parameters are calculated using ab-initio methods.

## 3 Experimental details

### 3.1 2-Aminopurine

#### 3.1.1 Sample preparation

**NMR sample preparation** DNA strands were obtained (from BIOTEZ, Berlin, and BIOSPRING, Frankfurt/M, Germany) already purified by reverse-phase high-pressure liquid chromatography (HPLC). After hybridization they were subjected to size exclusion chromatography (SEPHADEX G25) and ammonia treatment (lyophilization with  $\approx 3\%$   $\text{NH}_3$ -solution) to remove residual, low molecular weight impurities (mainly  $\text{Et}_3\text{N}$ -buffer from HPLC). Equivalent amounts of complementary single strands were hybridized by rapid heating to  $90^\circ\text{C}$  and subsequent gradual cooling to room temperature at a rate of  $1^\circ\text{C}$  per minute. NMR samples were prepared at 3 mM duplex concentration in  $\text{D}_2\text{O}$  ( $\text{D}_2\text{O}$  99.98 %) and  $\text{H}_2\text{O}$  ( $\text{H}_2\text{O}:\text{D}_2\text{O}/90:10$ ) at pH 6.5 in 10 mM  $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$  and 150 mM NaCl solution.

**RDC sample preparation** Samples for measuring residual dipolar couplings (RDC) were prepared in  $\text{D}_2\text{O}$  as described above with the addition of 20 mg/ml Pf1 (obtained from ASLA BIOTECH, Riga) suspended in the same buffer. This necessitates rebuffering of Pf1 since it is obtained in a different and non-deuterated buffer. Rebuffering is achieved by ultracentrifuging 100  $\mu\text{l}$  of Pf1 two times with 600  $\mu\text{l}$  phosphate buffer (as described above) and subsequently two times with 600  $\mu\text{l}$  deuterated phosphate buffer at 60000 rpm. Each ultracentrifuging step is performed at  $4^\circ\text{C}$  for 2 h. Next the sediment is suspended in the DNA sample. The high viscosity of Pf1 complicates sample handling and thus the suspension has to be stirred until a viscose, clear, gel-like sample is obtained. After

### *3 Experimental details*

transferring it into the NMR tube, bubbles have to be removed by slow centrifugation of the NMR tube (max. 500 rpm). The degree of orientation can be checked by measuring the quadrupolar deuterium splitting of the HOD signal [Lipsitz and Tjandra, 2004]. In case of degradation or non-complete suspension of Pf1 in the sample, the expected symmetric doublet with splitting of  $10 \pm 5$  Hz is asymmetric, extremely broadened or even non-observable.

### 3.1.2 Measurements

**Duplex melting** Melting of the 13mer2AP duplex was monitored by optical absorption at 260 nm and by the fluorescence quantum yield (due to the 2AP nucleobase) from 310 nm excitation [Evans et al., 1992]. For comparison, melting of the 13merRef duplex was measured by absorption only. The solutions had a total single-strand concentration of 23.7 mM and the optical path length was 1 cm. Temperature was varied between 25 and 85 °C; the standard error of transfer between absorption and emission temperatures was  $\pm 0.011$  °C. Following changes of typically 1 °C, equilibration was allowed for at least 15 minutes. The relative fluorescence yield of pure 2AP in buffered water was measured in the same manner for reference. Measurements were corrected for density changes.

**Imino proton exchange** Exchange rates of the imino protons were obtained from inversion recovery experiments at 298 K on a BRUKER AVANCE 600 NMR spectrometer. For this purpose the standard 1D <sup>1</sup>H-WATERGATE (water suppression by gradient tailored excitation) pulse program was modified to start with a selective inversion pulse. As discussed in section 2.2.2 the pulse shapes least sensitive to relaxation effects are rectangular and gaussian pulses. Dornberger et al. [1999] and Bhattacharya et al. [2002] use millisecond gaussian-shape pulses for inversion, but such long pulse durations again facilitate relaxation effects. Additionally, the imino protons are shifted upfield ( $\approx 13$  ppm) of the bulk of the DNA (1-9 ppm) and especially the HOD ( $\approx 4.80$  ppm) NMR signals and thus off-resonance excitation effects can be ruled out. In consequence, a selective rectangular inversion pulse of 327  $\mu$ s duration centered on the imino proton region was employed in this work. After a variable delay with 21 settings ranging from  $\tau=20$   $\mu$ s up to 2 ms, a 1D spectrum was recorded. The settings for the variable delay have been optimized to give accurate results for slowly as well as fast exchanging imino protons.

Samples were prepared in H<sub>2</sub>O with the buffer described earlier. In order to cancel the effect of intrinsic catalysis (cf. section 2.2.1), the spin-lattice relaxation time  $T_1^{int}$  of all imino protons was measured prior to titration with base catalyst. Subsequently, each duplex was titrated with 1 M TRIS buffer as base catalyst for proton exchange. Test runs

### 3 Experimental details

with ammonia as base catalyst gave inferior results, since the latter is highly volatile. This makes high-concentration salt solutions of ammonia, which are necessary in order to keep the pH stable upon addition of the catalyst, inaccessible. Another set of test runs, where pure ammonia and HCl (for pH compensation) were added separately to the NMR sample, resulted in temporary but extreme pH changes (pH values ranging from 1 to 11). These changes led to gradual degradation of the DNA sample. Furthermore, the error in concentration introduced by evaporation of ammonia is intolerable when high precision results are to be obtained. In order to keep the pH as stable as possible, TRIS-hydrochloride at pH 7.4 was used. At every titration point the pH was measured in order to determine the amount of free base catalyst precisely (cf. eq. (2.15 in section 2.2.1). All pH values centered around 7.1. To estimate the error in  $T_1$ -determination, three sets of measurements were carried out at each titration point, resulting in 693 1D spectra (21 delay settings, 11 titration points).

Each spectrum was fitted (with the MATHEMATICA program environment) to give the integrals of the imino proton peaks. Complete spectral fitting became necessary since standard region integration as implemented in TOPSPIN is sensitive to peak overlap. Due to continued broadening of the imino proton signals upon base catalyst addition, integrals obtained by the latter method were inconsistent and thus gave rise to large errors (up to 100 %) in  $T_1$ -values. In contrast, complete spectral fitting in MATHEMATICA yielded  $T_1$ -values with errors of typically 0.5-5 %.

**Structural NMR** NMR measurements for structure calculation were carried out on a BRUKER AVANCE 600 NMR spectrometer. The optimum temperature of 298 K was determined by monitoring the imino proton signal intensity (cf. Fig. 3.1). For each duplex, NOESY-, DQF-COSY- (double quantum filtered correlated spectroscopy), TOCSY- (total correlation spectroscopy) and HMQC-spectra (heteronuclear multiple quantum coherence spectroscopy) in  $D_2O$ , a WATERGATE-NOESY-spectrum in  $H_2O$  and an HMQC-spectrum in  $D_2O$ /Pf1 were recorded. The quadrupolar splitting of the  $^2H$  NMR signal after addition of Pf1-phage was 15.72 Hz and 13.65 Hz for 13merRef and 13mer2AP, re-

Fig. 3.1: Imino proton signal intensities for the temperature range 283-328 K. in 13mer2AP.

spectively. Upon addition of Pf1, the sample became very viscous and standard shimming procedures failed to produce reasonable linewidths. Two workarounds were investigated. One was to optimize the shim for a BRUKER standard sample and use these shim settings on the DNA/Pf1 sample. The second workaround involved optimization of the lineshape of the HOD signal. This procedure demands that after every change of the shim settings, a 1D spectrum of the sample had to be acquired. Although the latter procedure is more time-consuming than the other one, it yielded supreme results and thus was employed.

For DQF-COSY- (TOCSY-) spectra, 16 (32) transients were acquired, with  $2048 \times 256$  points in F2 and F1 dimensions. For NOESY-spectra in both solvents, 16 transients were acquired with  $4096 \times 2048$  points at a mixing time of 150 ms. For the HMQC-spectra with and without Pf1, 192 transients were acquired with  $8192 \times 512$  points. The high number of data points was necessary to obtain sufficient resolution in the proton dimension in order to determine the RDC-values with a precision below 1 Hz. The optimal d2-delay, where both the non-aromatic and aromatic region are equally enhanced, was determined to be 2.5 ms. All spectra were processed with the BRUKER TOPSPIN-software, and signals were assigned with the help of CARA [Keller, 2004].

#### 3.1.3 Restraint generation

**Force field parametrization** Density functional theory (DFT) calculations of the 2AP-nucleotide were performed with GAUSSIAN03 employing a triple zeta valence plus polarisation (TZVP) basis set. Due to the structural proximity of 2AP and A, force field parameter and topology entries of the latter were adopted and changed where necessary. Special emphasis was placed on the charge distribution since this was shown to be the main difference between A and 2AP [Broo, 1998, Mishra et al., 2000, Jean and Krueger, 2006]. For this purpose several methods for obtaining point charges were compared. The fastest method is the Mulliken population analysis, which, however, gives unrealistic results [Breneman and Wiberg, 1990]. This is due to the equal distribution of overlap populations between the two involved atoms. Hence another approach has been developed, which tries to derive atomic charges via fitting of point charges to the Molecular Electrostatic Potential (MEP) [Connolly, 1983, Singh and Kollman, 1984]. Crucial to the success of this technique is the algorithm which is used for fitting. Three different algorithms were tested; the CHELP- [Chirlian and Francl, 1987], the CHELPG- [Breneman and Wiberg, 1990] and the MK-algorithm [Besler et al., 1990]. Out of these three the MK- and CHELPG-algorithms gave consistent and similar results. Partial charges derived with the CHELPG-algorithm were employed in the force field. Although the sugar moiety was simulated as well, only the partial charges for the 2AP residue were integrated into the force field. Due to the similarity of A and 2AP the influence of the latter on the partial charges of the sugar can be considered negligible (as the same values for partial charges of sugar atoms are also used for G,C and T residues). Thus the partial charge values for the sugar were taken as already defined for the native residues in the force field. To retain the neutrality of the 2AP residue the partial charge at the N7 atom of 2AP was increased from -0.61 to -0.45 (cf. section 3.1.3).

**Distance restraints** The assigned NOE cross-peaks were converted to distance restraints by referencing their integrals to the integrals of known distances employing the Isolated Spin Pair Approximation. The NOE cross-peaks were integrated with the pro-

gram CARA [Keller, 2004] using the sum-over-rectangle method. As reference distances Me-H6 T (3.1 Å) for all NOE cross-peaks involving methyl protons, H42-H5 C (2.4 Å) for all NOE cross-peaks involving exchangeable protons and H5-H6 C (2.5 Å) for the remaining NOE cross-peaks were used (bond lengths adapted from the force field parameters). For the purpose of exporting the integral values obtained by CARA [Keller, 2004] to an XPLOR-NIH [Schwieters et al., 2003] restraints file, a LUA script was written (see section .4). This script classifies the integrated peaks according to the overlap with other peaks and scales their volume integrals accordingly. Additionally, uncertainties for the NOE restraints are automatically calculated from the standard deviation of the reference peaks' volume integrals. The estimated uncertainty is then increased according to the classification of each peak. Furthermore, this classification is printed into a separate file, which can be used to assess whether or not peak overlap might prevent a reliable estimation of the peak volume.

**Residual Dipolar Coupling restraints** The experimentally determined RDCs (see tables 3.1 and 3.2) of C-H bond vectors can be input into the structure calculations with the measurement precision as error bounds. From the experimentally determined RDC-values the orientation of the corresponding internuclear vector is determined via eq. (2.39) in section 2.3.3. All constants in the latter equation are comprised within the factor  $D_a$

$$D_a = -\frac{\gamma_i \gamma_j \mu_0 \hbar S_{flex}}{4 \pi^2 (r_{ij}^{eff})^3} \quad (3.1)$$

for which only one value is used throughout the calculation. This necessitates scaling of different sets of RDCs, for example when C-H as well as C-C RDCs have been measured. Scaling is achieved by introducing prefactors to the  $D_a$ -factor, which are defined as the ratio of the two  $D_a$ -factors involved. For example, when C-C RDCs are to be scaled to a set of C-H RDCs, the corresponding prefactor would be calculated as:

$$D_a^{pre}(CC) = \frac{D_a(CH)}{D_a(CC)} = \frac{\gamma_H}{\gamma_C} \left( \frac{r_{CC}}{r_{CH}} \right)^3 = \frac{42.576}{10.705} \left( \frac{1.496}{1.090} \right)^3 \approx 10.28 \quad . \quad (3.2)$$

### 3 Experimental details

where  $\frac{\gamma_H}{\gamma_C}$  is the change in gyromagnetic ratio when working with C-H or C-C RDCs and  $r_{CC}$  and  $r_{CH}$  are the C-C and C-H bond lengths between the atoms defining the internuclear vector. Although in this work only C-H RDCs were measured, scaling issues become important for the implementation of the experimentally determined C-H RDCs of the T methyl groups.

Due to the fast rotation of the latter, only an averaged value for all three C-H bond vectors can be measured. This fast rotation scales the corresponding RDC values by

$$P_2(\cos\beta) = \frac{3}{2} \cos^2\beta - \frac{1}{2} \quad (3.3)$$

where  $\beta$  is the C5-C7-H7\* angle. The latter is usually assumed to be the ideal tetrahedral angle of  $109.5^\circ$ , but was experimentally determined for methyl groups to be  $110.9^\circ$  by Ottiger and Bax [1999b]. Although small, the deviation from the ideal angle has a strong impact on methyl RDC scaling since  $P_2(\cos\beta)$  is a steep function  $\beta$ . Thus with  $P_2(\cos 109.5) = -0.3329$  and  $P_2(\cos 110.9) = -0.3089$ , conversion factors between C5-C7 and C7-H7\* methyl RDCs can be calculated as -3.42 and -3.17, respectively, according to

$$\frac{D_{CH\_Me}}{D_{CC\_Me}} = P_2(\cos\beta) D_a^{pre}(CC) \quad (3.4)$$

The value of -3.17 was determined by measuring the correlation of experimentally determined C-H and C-C methyl RDCs [Ottiger and Bax, 1999b].

In order to implement the methyl C-H RDCs into the structure calculations, they have to be associated with a unique internuclear vector. Thus it is necessary to convert the C7-H7\* RDCs into the corresponding C5-C7 RDCs. Since the latter must now be input as C-C RDCs, a separate restraints file has to be used. There are in principle two ways how this implementation can be achieved in XPLOR-NIH v2.20 [Schwieters et al., 2003]. One way is to convert all experimentally determined methyl C-H RDC values by hand to the corresponding C-C values with the factor  $1 / -3.17 = -0.3155$ . This is done prior to implementing them into the calculation. In that case, the prefactor  $D_a^{pre}(CC)$  can be used to scale the C-C RDC input file to the C-H RDC input. According to the manual,

this scaling is handled automatically by the *scale\_toCH* routine of the program XPLOR-NIH v2.20 [Schwieters et al., 2003]. Due to a bug however, the automatic scaling is only effective when the methyl C-C RDCs are input as type “CACO”. The other way to input C-H methyl RDCs into structure calculations will be implemented in the new version of XPLOR-NIH (v2.24) but was made available to the author in advance (personal communication of Dr. Charles Schwieters). In that new version, the methyl RDCs are input as a separate restraints file too, but their values do not have to be scaled by hand. They are automatically recognized by the program as methyl RDCs and scaled to the C-H RDC input by

$$D_{Me}^{pre} = -3.17 D_a^{pre}(CC) = 32.59 \quad . \quad (3.5)$$

However, scaling of the  $D_a$ -factor and scaling the RDC values is not equivalent, since the energy for the RDC potential term is given by [Brünger, 1996]

$$E_{RDC} = k_{RDC} (D_{calc} - D_{obs})^2 \quad (3.6)$$

where  $k_{RDC}$  is the scale factor for the RDC energy term. The latter must be modified for different sets of RDCs according to their respective errors with a weighting factor  $\omega_{ij}$ . When using the prefactor  $D_{Me}^{pre}$  for implementation of methyl RDCs, the energy of the C-C methyl RDCs has to be scaled by

$$\omega_{CC} = \frac{1}{(-3.17)^2} \omega_{CH} = 0.0995 \omega_{CH} \quad (3.7)$$

due to dependence of the energy on the square of the difference between calculated ( $D_{calc}$ ) and observed ( $D_{obs}$ ) RDC.

### 3.1.4 Structure calculation

**Calculation input** Structure calculations were performed with XPLOR-NIH v2.20 [Schwiete et al., 2003]. A total of 340 (333) NOE distance restraints and 24 (25) Residual Dipolar Couplings were used for 13merRef (13mer2AP). The experimental data were supplemented with 144 backbone dihedral restraints, 78 hydrogen bond distance restraints and 28 planarity restraints (see Table 3.3).

Initial MD-calculations were performed with dihedral restraints allowing both A-form and B-form conformations (with error bars of  $\pm 50^\circ$ ). B-form conformation was experimentally confirmed by  $^3J$  coupling constants for H1'-H2' derived by P.E.COSY (primitive exclusive correlated spectroscopy) and NOESY-cross-peak intensities characteristic of B-DNA. Consequently, regular dihedral values from the literature [Roberts, 1993] were included in the calculations.

**Tabelle 3.3:** Overview of structural statistics for 13merRef and 13mer2AP calculations

	13merRef	13mer2AP
<b>NOE restraints</b>		
- total	340	333
- interresidue	196	188
- intraresidue	144	145
- 2AP to DNA	-	9
<b>RDC restraints</b>	24	25
<b>Dihedral angle restraints</b>	144	144
<b>H-bond restraints</b>	78	78
<b>Base pair planarity restr.</b>	28	28
<b>NOE viol. (<math>&gt; 0.5 \text{ \AA}</math>)</b>	0	0
<b>RDC viol. (<math>&gt; 0.4 \text{ Hz}</math>)</b>	0	0
<b>Dihe viol. (<math>&gt; 5^\circ</math>)</b>	0	0
<b>RMSD to ave. struct. in <math>\text{\AA}</math></b>	0.30	0.33

The structures were calculated in two steps. First, a reasonable starting structure with well defined local conformation was computed. To ensure that no bias is introduced towards local energy minima, the calculation started from an elongated and equilibrated structure. The resulting structure, which is mainly defined by NOE restraint data, was used as input for Simulated Annealing calculations including RDC data. The need for locally well defined starting structures in order to calculate reasonable structures which

satisfy NOE as well as RDC data is documented in the literature [Vermeulen et al., 2000, Mauffret et al., 2002].

**Simulated Annealing protocol** The two complete MD protocols are given in the Appendix, section .2. Only the protocols for the 13mer2AP calculation is given, since the other calculations were carried out with the same protocol (with the exception of the input file names). The input scripts are based on the example files of the XPLOR-NIH package (`refine_full.py` and `sa.inp`) but were substantially modified in the course of this work.

The MD protocol with only NOE restraints as experimental input consisted of an initial minimization (50 steps) followed by 48 ps of high-temperature cartesian coordinate dynamics at 3000 K, subsequent gradual cooling to 25 K in 120 steps of 0.05 ps length and a final minimization (3000 steps).

The MD protocol including the experimental RDC restraints consisted of an initial cartesian coordinate minimization (1000 steps) followed by 50 ps of high-temperature cartesian coordinate torsion angle dynamics at 20000 K, subsequent gradual cooling to 25 K in 154 steps of 0.5 ps length (34 steps to cool down to 3000 K, followed by 120 steps to reach the end temperature) and a final minimization (3000 steps). The alignment tensor values were allowed to float during the calculations, as implemented in XPLOR-NIH (v2.20) [Schwieters et al., 2003].

For each run an ensemble of 100 structures was computed. The 10 minimum energy structures without violation of restraints were chosen to compute an averaged structure which was energy-minimized to yield the final structure. The root-mean-squares-deviation (RMSD) of the 10 minimum energy structures to the average, minimized structure is a measure for the precision of the calculation.

**Structure validation** To check the accuracy of the structures, NOESY-spectra were back-calculated from the average structures with the Full Matrix Relaxation Approach implemented in XPLOR-NIH (v2.20) [Schwieters et al., 2003]. The back-calculated spectra were visualized with the program GIFA [Pons et al., 1996] and overlayed with the

### *3 Experimental details*

experimental ones. Furthermore, RDCs were predicted from the average structure using the program PALES [Zweckstetter and Bax, 2000] and compared to the experimental ones. Finally, helical parameters were calculated with the help of the program 3DNA [Lu and Olson, 2003]. These were checked for consistency with values for regular B-DNA helices.

A number of convenience scripts were written to automate data conversion between PALES [Zweckstetter and Bax, 2000] and XPLOR-NIH (v2.20) [Schwieters et al., 2003], the latter program and GIFA [Pons et al., 1996] and for quick access to energies or number of restraints in structure calculations output files. These utility scripts are comprised in the Appendix in section .5.

## 3.2 2-Hydroxy-7-nitrofluorene

Since many experimental details for HNF are equivalent to the ones for 2AP, the description for the latter is referenced where appropriate in order to avoid redundancy.

### 3.2.1 Sample preparation

2-Hydroxy-7-nitro-fluorene was synthesized (Matthias Pfaffe) in four steps. The 2'-deoxyriboside dRi-HNF was prepared by reaction with 1'- $\alpha$ -Chloro-3',5'-di-O-toluoyl-2'-deoxy-D-ribose in the presence of activated molecular sieve. Quantification of the H1'-H2'/H2'' and H3'-H2'/H2'' NOE cross-peaks in the NOESY-spectra of the main product revealed that the  $\alpha$ -glycoside was formed predominantly. After purification of the latter by column chromatography, the corresponding phosphor-amidite was reached by standard methods. Fixed-phase synthesis of the labelled DNA strand (BIOTEZ) required a fourfold increase over the normal reaction time for coupling dRi-HNF. Further sample preparation is equivalent to the one described in section 3.1.1.

### 3.2.2 Measurements

**Duplex melting** Melting of the 13merHNF duplex was monitored by optical absorption at 260 nm and by the red-shift of the weak absorption band of HNF at 380 nm. The solution had a total single-strand concentration of 23.5 mM and the optical path length was 1 cm. The following procedures are equivalent to the ones described in section 3.1.2.

**Structural NMR** NMR measurements for structure calculation were carried out on a BRUKER AVANCE 600 NMR spectrometer at 298 K. For each duplex, NOESY-, DQF-COSY-, TOCSY- and HMQC-spectra in D<sub>2</sub>O, a WATERGATE-NOESY-spectrum in H<sub>2</sub>O and an HMQC-spectrum in D<sub>2</sub>O/Pf1 were recorded. The quadrupolar splitting of the <sup>2</sup>H NMR signal after addition of Pf1-phage was 10.55 Hz. The following procedures and settings are equivalent to the ones described in section 3.1.2.

### 3.2.3 Restraint generation

Distance restraints, RDC restraints and force field parameters were generated as described in section 3.1.3. The experimental RDC values that were used for restraint generation are given in Table 3.4. In the case of HNF however, no topology information for a structurally similar compound was available. Thus the corresponding parameter and topology input files had to be generated from the structure calculated by DFT methods as described in section 3.1.3. The latter can be achieved utilizing the program XPLO2D [Kleywegt and Jones, 1998].

The influence of the HNF on the partial charges of the sugar residue was considered to be non-negligible for C1' and the directly bonded atoms due to the strong structural and electronic differences between native nucleobases and HNF. Thus, in contrast to 2AP, for the atoms C1', C4', H4', H1'', and O4' of HNF the partial charges derived from the DFT-calculations were used. The charge at O4' was increased by +0.13 in order to retain neutrality of the residue (cf. section 3.1.3).

**Tabelle 3.4:** Experimentally determined RDCs for 13merHNF. The RDCs were measured with a precision of  $\pm 0.6$  Hz.

### 3.2.4 Structure calculation

The Simulated Annealing protocol and Structure validation were carried out as described in section 3.1.4.

**Calculation input** Structure calculations were performed with XPLOR-NIH v2.20 [Schwitters et al., 2003]. As the HNF was found to exist in two different orientation with in the duplex, two calculation runs were performed with the HNF methylene group pointing towards the major or minor groove for face-up and face-down orientations, respectively. A total of 401 (403) NOE distance restraints and 19 Residual Dipolar Couplings were used for the calculation of the face-up (face-down) orientation. The experimental data were supplemented with 124 backbone dihedral restraints, 72 hydrogen bond distance restraints and 24 planarity restraints (see Table 3.5).

Initial MD-calculations were performed with dihedral restraints, allowing both A-form and B-form conformations (with error bars of  $\pm 50^\circ$ ). B-form conformation was experimentally confirmed by NOESY-cross-peaks intensities characteristic of B-DNA. Consequently, regular dihedral values from the literature [Roberts, 1993] were included in the calculations for all but the HNF residue.

**Tabelle 3.5:** Overview of structural statistics for 13merHNF calculations

## 4 Results and discussion

### 4.1 2-Aminopurine

#### 4.1.1 Introduction

2AP is known since the 1950s for its role in the mutagenic transition of A:T to G:C base pairs [Freese, 1959, Rogan and Bessman, 1970, Ronen, 1979]. As a structural isomer of A it can form stable WC-type base pairs with T (see Fig. 4.1) [Ronen, 1979, Sowers et al., 1986]. Base pairs with C, A or G are much weaker [Sowers et al., 1986, Fazakerley et al., 1987, Hochstrasser et al., 1994, Law et al., 1996]. Thus 2AP is incorporated instead of A by DNA polymerase opposite to T [Freese, 1959], though at a

lower frequency than A [Rogan and Bessman, 1970, Watanabe and Goodman, 1982]. The mutagenic transition of A:T to G:C occurs during replication of 2AP:T base pairs [Bernstein et al., 1976, Goodman et al., 1977]. By adjusting the type of polymerase [Grossberger and Clough, 1981] or the concentration of nuclease [Clayton et al., 1979] the mutagenic rate can be tuned. The influence of nucleotide sequence on the mutagenic rate has no discernable logical pattern [Pless and Bessman, 1983]. Another way to stimulate the mutagenic transition is to increase the dCTP- or decrease the TTP-level

**Fig. 4.1:** DNA duplex sequence with chemical structure of the 2AP-T and A-T base pairs.

#### 4 Results and discussion

in the cell [Caras et al., 1982]. In 1981 Watanabe et al. [Watanabe and Goodman, 1981] demonstrated that 2AP:C mispairs form at 320-fold higher frequency than A-C mispairs. They concluded that 2AP:C mispairing is central to the mutagenicity of 2AP.

The stabilization of the 2AP:C base pair in solution therefore had to be investigated. Four models have been proposed for the geometry of this mispair. Ronen [1979] suggested a WC geometry with one hydrogen bond, while Goodman and Ratliff [1983] presented evidence for two hydrogen bonds involving one of the bases in the rare tautomeric imino form. Sowers et al. put forth the other two pairing schemes. Based on NMR imino proton data and pH-titration experiments, they proposed WC geometry through protonation of the mispair at neutral pH [Sowers et al., 1986]. A  $^{15}\text{N}$ -enriched NMR-study later suggested a wobble geometry at high pH [Sowers et al., 1989], corroborated by fluorescence anisotropy measurements which showed pH-dependent conformational changes in the geometry of the 2AP:C mispair [Guest et al., 1991].  $^{15}\text{N}$ -enriched NMR-studies by Fagan et al. [1996] and Sowers et al. [2000] reproduced this pH-dependence and could finally demonstrate that the wobble geometry is predominant at neutral pH while protonation occurs sequence-dependently at lower pH. This conclusion is supported by a theoretical study [Sherer and Cramer, 2001].

The fluorescence properties of 2AP differ markedly from those of the natural nucleobases [Longworth et al., 1966, Callis, 1979, Serrano-Andres et al., 2006]. This was recognized originally by Ward et al. [1969] who observed a decrease in quantum yield of fluorescence by two orders of magnitude upon stacking of 2AP in a DNA helix. The effect was first exploited to determine thermodynamic parameters of stacking associations by Bierzynski et al. [Bierzynski et al., 1977b,a, Gajewska et al., 1982].

Fluorescence quenching of 2AP can also be used to study structural transitions in biological systems [Ward et al., 1969]. At the beginning such applications were thwarted by the lack of site-specific incorporation techniques. After chemical synthesis of 2AP-containing DNA-duplexes was realized [Eritja et al., 1986, McLaughlin et al., 1988], fluorescence quenching of 2AP was employed to study structural transitions in DNA [Lycksell et al., 1987, Patel et al., 1992]. In 1993 Bloom et al. [Bloom et al., 1993, 1994] were the

first to use 2AP fluorescence quenching to follow the kinetics of polymerase-catalyzed 2AP-insertion on a millisecond timescale. But on the whole, fluorescence quenching of a 2AP nucleobase surrogate is used to detect base stacking-unstacking transitions.

The local dynamics in the vicinity of 2AP, and its variation with sequence, can be studied by monitoring the fluorescence anisotropy decay [Nordlund et al., 1989]. This technique was used by Guest et al. [1991] to characterize the dynamic behaviour of mismatched base pairs. Hochstrasser et al. [1994] combined both techniques - fluorescence quenching and anisotropy decay - to study DNA double strand melting upon binding to the Klenow fragment. Xu et al. [1994] utilized 2AP fluorescence to show that DNA duplex melting proceeds via a highly flexible, yet B-DNA type transition state.

Numerous studies - facilitated by improved synthesis [Fujimoto et al., 1996] and subsequent commercial availability of 2AP-containing oligonucleotides - exploit 2AP fluorescence to investigate various problems in structural biology and biophysics: methyltransferase-induced base flipping [Allan and Reich, 1996, Allan et al., 1998, Holz et al., 1998, Allan et al., 1999, Stivers et al., 1999, Gowher and Jeltsch, 2000, Reddy and Rao, 2000, Bernards et al., 2002, Daujotyte et al., 2004, Su et al., 2004, Neely et al., 2005, Lenz et al., 2007], conformational changes and enzymatic cleavage of the hammerhead ribozyme [Menger et al., 1996, 2000, Kirk et al., 2001], promoter binding and clearance of T7 RNA polymerase [Jia et al., 1996, Ujvari and Martin, 1996, Bandwar and Patel, 2001, Liu and Martin, 2002], binding and strand separation of primer-template DNA by T4 DNA polymerase [Marquez and Reha-Krantz, 1996, Beechem et al., 1998, Fidalgo da Silva et al., 2002, Mandal et al., 2002, Hariharan and Reha-Krantz, 2005, Hariharan et al., 2006, Tleugabulova and Reha-Krantz, 2007], and charge transfer mechanisms together with polar solvation in DNA [Kelley and Barton, 1999, Wan et al., 2000, Fiebig et al., 2002, Jean and Hall, 2002, O'Neill and Barton, 2002a,b, Jean and Hall, 2004, O'Neill and Barton, 2004, Hardman and Thompson, 2006, Jean and Krueger, 2006, Hardman and Thompson, 2007]. All of these studies utilize 2AP fluorescence.

A new possibility to study structural transitions in biomolecules has recently been devised which makes use of unique properties of 2AP. Johnson et al. [2004] demonstrated

#### 4 Results and discussion

that a low-energy Circular Dichroism band is observed for 2AP dinucleotides incorporated into DNA or RNA double strands. They used this method to monitor structural changes in RNA hairpin loops [Johnson et al., 2005b] or breathing fluctuations at replication forks [Johnson et al., 2005a]. This new technique and the high number of 2AP-related publications show the significance of 2AP for the study of biological macromolecules.

Structure perturbation upon incorporation of 2AP into a DNA-helix was investigated in detail only once, by Nordlund et al. [1989]. A palindromic sequence containing two 2AP:T base pairs was investigated by NMR spectroscopy, fluorescence decay and Molecular Dynamics simulations. Base pairing is observed in the duplex, but the melting temperature of the duplex was considerably lower than in the reference with WC A:T base pairs. The missing of NOE-crosspeaks to the 5'-side of the 2AP-substitution was interpreted as a local disturbance of the overall B-type helix [Nordlund et al., 1989]. Studies on minor groove binding drugs support this conclusion. They indicate that 2AP incorporation into A-T tracts reduces the binding affinities of these drugs to the level of G-C tracts [Loontjens et al., 1991, Patel et al., 1992]. Minor groove distortions by 2AP have also been proposed by a theoretical study [Lankas et al., 2002].

Dynamical effects due to incorporation of 2AP were examined even more scarcely. Nordlund et al. [1989] reported efficient recognition and cleavage of 2AP-containing duplexes by EcoRI, and concluded that dynamics are not perturbed. On the contrary, Lycksell et al. [1987] observed a 1 ms lifetime for the 2AP:T base pair, lower than for the corresponding A:T base pair, but state that the accuracy is correct probably only within a factor of 2. A destabilizing effect on the neighbouring pairs was not observed.

When structural transitions in biological systems are studied with a molecular probe, the assumption is that the modified system behaves like the natural one. Consequently the introduction of the probe must leave the structure unchanged. Disturbance of the original helix when 2AP occupies an A site would limit or even prevent the use of 2AP-fluorescence in some studies of biological systems. Therefore the above-mentioned hypothesis of a local disturbance has to be tested.

For this purpose a detailed analysis of the solution structure of a DNA-duplex in which

an A is substituted by 2AP is presented. The only change introduced into the helix is the difference in the position of the amino group of A and 2AP (cf. Fig. 4.1). In contrast to previous studies [Lycksell et al., 1987, Nordlund et al., 1989] the nonpalindromic nature of the sequence allows to have a single perturbation site. Thus any change in structure or base pair dynamics can be directly attributed to the 2AP incorporation. The central base pair was modified in order to detect possible long-range effects (up to three base pairs) of 2AP incorporation, which otherwise might be rendered ambiguous due to base pair fraying effects [Nonin et al., 1995]. A symmetric 13 base pair sequence was chosen to dismiss the possibility of mispairing, loop formation and fraying effects.

## 4 Results and discussion

**Fig. 4.2:** Sequential assignment in the sugar H1' base H6/H8 region of the NOESY-spectrum in  $D_2O$  for 13merRef (a) and 13mer2AP (b). Only the intraresidual cross-peaks H1'-H6/H8 are marked for clarity. Starting points are marked with blue, end points with red circles. All cross-peaks expected for a regular B-DNA helix are observed for both duplexes.

### 4.1.2 Results

#### 4.1.2.1 Chemical shift analysis

The NOESY-spectra were assigned with the sequential approach [Roberts, 1993, Bloomfield et al., 2000]. The sequential assignments of the sugar H1' and base H6/H8 protons for 13merRef and 13mer2AP are shown in Fig. 4.2a and 4.2b, respectively. Cross peaks expected for a regular B-DNA helix are present in the NOESY-spectra of both samples. Based on the assignment of the H1' and H6/H8 protons, the remaining base and sugar protons could be assigned by combining the information from the COSY-, TOCSY-, HMQC-, and NOESY-spectra. Assignment of the exchangeable protons was done in the WATERGATE-NOESY-spectrum. The imino proton of T20 was easily identified, because of the symmetry of the sequence, but the remaining imino, amino, and H2 protons had to be referenced to the already assigned non-exchangeable C H5 protons via the H42/H41-H5 NOE cross-peaks.

$^1H$  Chemical Shift Differences (CSDs) between 13merRef and 13mer2AP are negligible ( $< 0.10$  ppm) for all but the H1', imino, and H2 protons of the central three base pairs (see Table 4.1 and Table .13 in the Appendix, section .10). There is no significant trend that either 3'- or 5'-neighbours exhibit larger CSDs. No CSDs for the H6 and H8 protons

**Tabelle 4.1:** Selected  $^1\text{H}$  Chemical shift differences (CSD) (reference HOD at 4.80 ppm, calculated as  $X(13\text{merRef}) - X(13\text{mer2AP})$ ) for 13merRef and 13mer2AP. Only the inner 7 base pairs are shown. In the case of X7 H2 the difference between the chemical shifts of H2 (A) and H6 (2AP) is taken.

for purine and pyrimidine bases with the exception of residues A7/2AP7 are observed.

In Fig. 4.3 the sum of the absolute values of the CSDs of all protons belonging to one residue is given for 13merRef to 13mer2AP (blue columns) and 13merRef to 13merRefGC (red columns). In 13merRefGC the central base pair of 13merRef is substituted by G:C. With the exception of the modification site, absolute per-residue CSDs from 13merRef to 13mer2AP are smaller than to 13merRefGC. Per-residue CSDs are significant two bases in each direction from the modification site in the 2AP-containing strand. In the unmodified counterstrand only the central three T bases exhibit significant CSDs. The chemical shifts of all assigned protons and carbons for 13merRef and 13mer2AP are given in the Appendix, sections .8 and .9, respectively.

**Fig. 4.3:** The sum of the absolute values of the CSDs of all protons belonging to one residue is given for: 13mer2AP to 13merRef (blue columns) and 13merRef to 13merRefGC (red columns) for comparison.

**Fig. 4.4:** Overlay of the 10 best-energy, minimum-violation structures for 13merRef and 13mer2AP. The RMSD among each set of structures is 0.30 Å and 0.33 Å, respectively. The average structures for the two duplexes are compared in the middle; their RMSD is 0.46 Å.

#### 4.1.2.2 Structural comparison

From a family of 100 calculated structures the 10 minimum-energy, violation-free structures are shown in Fig. 4.4 for 13merRef (left) and 13mer2AP (right). The latter were used to calculate an average structure each. The accuracy of the calculations was checked by back-calculating the NOESY-spectrum from the average structure, followed by comparison with the experimental spectrum (Fig. 4.5a and 4.5b). Additionally, the RDCs were back-calculated from the average structure with the program PALES [Zweckstetter, 2008]. The correlation plots of experimentally determined vs predicted RDCs are shown in Fig. 4.6a and 4.6b and yielded correlation factors ( $R$ ) of 1.000 and q-factors of 0.002 and 0.003 for 13merRef and 13mer2AP, respectively. The precision of the calculations can be assessed by the RMSD of the 10 best structures from their average, 0.30 Å for 13merRef and 0.33 Å for 13mer2AP. An overlay between the averaged structures is shown in Fig. 4.4 (middle part); their RMSD is 0.46 Å.

Helical parameters were calculated for the 10 minimum-energy, violation-free structu-

## 4 Results and discussion

**Fig. 4.5:** Overlay of the experimental NOESY-spectrum at 150 ms mixing time (green) and the NOESY-spectrum back-calculated from the average structure (red). Arrows point to NOE cross-peaks involving the modification site.

**Fig. 4.6:** Plot of the experimental vs predicted RDCs for *13merRef* and *13mer2AP*.

**Fig. 4.7:** 13merRef and 13mer2AP: Differences ( $X(13\text{merRef}) - X(13\text{mer2AP})$ ) in translational helical parameters between base pair partners [Å]. Blue columns represent "Shear"-values, green ones "Stretch" and red ones "Stagger". Error bars indicate the estimated uncertainty.

**Fig. 4.8:** 13merRef and 13mer2AP: Differences ( $X(13\text{merRef}) - X(13\text{mer2AP})$ ) in rotational helical parameter between base pair partners [°]. Blue columns represent "Buckle"-values, green ones "Propeller Twist" and red ones "Opening". Error bars indicate the estimated uncertainty.

**Fig. 4.9:** 13merRef and 13mer2AP: Differences ( $X(13merRef) - X(13mer2AP)$ ) in translational helical parameter between base pairs [Å]. Blue columns represent "Shift"-values, green ones "Slide" and red ones "Rise". Error bars indicate the estimated uncertainty.

**Fig. 4.10:** 13merRef and 13mer2AP: Differences in rotational helical parameter between base pairs [°]. Blue columns represent "Tilt"-values, green ones "Roll" and red ones "Twist". Error bars indicate the estimated uncertainty.

res of 13merRef and 13mer2AP with the program 3DNA [Lu and Olson, 2003]. Fig. 4.7 and 4.8 depict differences between 13merRef and 13mer2AP in translational and rotational helical parameters between base pair partners, while Fig. 4.9 and 4.10 display differences in translational and rotational helical parameters between base pairs. The value ( $X$ ) represented by a column in Fig. 4.7- 4.10 is calculated as:

$$X = \frac{1}{10} \left( \sum_{n=1}^{10} X_n(13merRef) - \sum_{n=1}^{10} X_n(13mer2AP) \right) \quad (4.1)$$

where  $X_n(13merRef)$  and  $X_n(13mer2AP)$  represent the helical parameter values calculated for the 10 minimum-energy, violation-free structures of 13merRef and 13mer2AP, respectively. The RMSD of these values to their average is shown as an error bar. Thus a measure for the precision of a given helical parameter is obtained. In general, for translational parameters only values which deviate by at least  $0.1 \text{ \AA}$  (with the corresponding uncertainties taken into account) and for rotational parameters  $> 5^\circ$  are interpreted. Deviations below these thresholds are too weak to be reliably described by the force field (deviations of  $0.1 \text{ \AA}$  and  $5^\circ$  from the equilibrium value are allowed for bond lengths and angles respectively).

In the following, the observed perturbations in helical parameters are presented. For definition of the helical parameters please see section 2.1, Fig. 2.5.

- The “Stagger”-values (red columns in Fig. 4.7) differ significantly for base pairs G4:C23 ( $-0.23 \pm 0.09 \text{ \AA}$ ), A8:T19 ( $-0.18 \pm 0.07 \text{ \AA}$ ) and G10:C17 ( $0.24 \pm 0.06 \text{ \AA}$ ), while values for “Shear” and “Stretch” (blue and green columns in Fig. 4.7) do not show significant deviations.
- Of the rotational helical parameters within base pairs only the “Propeller Twist”-values (green columns in Fig. 4.8) of base pairs X7:T20 ( $-7.0 \pm 1.6^\circ$ ) and A8:T19 ( $-8.1 \pm 2.1^\circ$ ) exhibit significant deviations, while “Buckle”- and “Opening”-values are equal within the estimated error (blue and red columns in Fig. 4.8 respectively).
- The rotational helical parameters between base pairs “Tilt”, “Roll” and “Twist” (blue, green and red columns in Fig. 4.10 respectively) do not show significant variations within

#### 4 Results and discussion

the estimated error.

- The “Shift”-values (blue columns in Fig. 4.9) differ significantly for base pair steps C2:T3 ( $-0.26 \pm 0.10$  Å), A6:X7 ( $0.20 \pm 0.03$  Å) and A8:C9 ( $0.26 \pm 0.03$  Å). The “Slide”-values (green columns in Fig. 4.9) differ significantly for base pair steps T3:G4 ( $0.28 \pm 0.15$  Å), A6:X7 ( $0.22 \pm 0.11$  Å) and A8:C9 ( $-0.26 \pm 0.12$  Å). The “Rise”-values (red columns in Fig. 4.9) do not differ within the estimated confidence interval.

In summary, significant deviation in helical parameters are observed throughout the duplex, with the central three base pairs exhibiting the largest deviations. The average helical parameters calculated from the values for the 10 minimum-energy, violation-free structures of 13merRef and 13mer2AP are listed in the Appendix in sections .11 and .12, respectively.

## 4.1.2.3 Comparison of base pair dynamics

The T20 imino proton resonance behaves substantially different depending on the counter base 2AP or A. In 13mer2AP this resonance can be observed in the 1D-spectrum, though it is broadened substantially (cf. Fig. 4.12). The corresponding diagonal signal in the NOESY-spectrum however vanishes with increasing mixing time beyond 100 ms. Fig. 4.11 illustrates this unusual decay behaviour by comparing signal intensities for the diagonal and representative cross-peak signals of T20 (●) and T3 (▲) in 13mer2AP. Diagonal signals T20 H3 and T3 H3 (solid lines) are normalized at 50 ms to show their different decay behaviour. Wi-

**Fig. 4.11:** T20 (●) and T3 (▲) imino proton intensities for 13mer2AP at 298 K. Solid lines depict diagonal signals, while dashed lines represent cross-peak intensities of T20H3–2APH6 and T3H3–A24H2.

thout this normalization, the diagonal peak of T20 H3 reaches only 20 % of the T3 H3 signal intensity at 50 ms. Cross-peaks T20H3–2APH6 and T3H3–A24H2 (dashed lines) are given relative to the corresponding diagonal signal at 50 ms. The diagonal T20 H3 peak almost vanishes when going from 50 to 100 ms mixing time. The intensity of the NOE cross-peak to 2AP H6 decays slowly, in contrast to the T3H3–A24H2 cross-peak where the intensity increases for the first 200 ms.

To test whether H<sub>2</sub>O exchange is responsible for the unusual decay behaviour of T20 H3 we performed water saturation transfer experiments. In the latter experiments 1D-spectra in H<sub>2</sub>O are acquired with two different methods of attenuating the water signal. With the presaturation method the water signal is saturated before the actual pulse sequence (Fig. 4.12 (B,D): irradiation time 3 s, strength 55 dB). Consequently, exchange of now saturated water protons with unsaturated imino protons leads to attenuation of the latter signal. This cosaturation can be circumvented by using the WATERGATE

**Fig. 4.12:** Saturation transfer experiments in  $H_2O$ . Resonances from exchanging protons are reduced in the 1D presaturation spectra (lower black lines, B,D), reflecting the relative rates by which imino protons exchange with the solvent. Water saturation is avoided in 1D WATERGATE spectra which are shown for comparison (upper gray lines, A,C).

pulse sequence (Fig. 4.12 (A,C)), which does not excite the water protons and thus prevents their detection. Here water exchange with imino protons leaves their signal unperturbed. Fig. 4.12 depicts the imino proton region with both attenuation techniques, presaturation (B,D) and WATERGATE (A,C) for 13merRef, 13mer2AP respectively. In 13mer2AP the cosaturation of the T20 imino proton is so strong that the signal is not observable in presaturation experiments. The signals of the directly adjacent bases T19 and T21 are reduced in intensity when compared to the corresponding signals in 13merRef.

Base pair dynamics can be studied by measuring the base pair lifetime  $\tau_{op}$ . The latter is obtained by extrapolating a plot of imino proton exchange  $\tau_{ex}$  vs inverse base concentration  $1/[B]$  to infinite catalyst concentration (for explanation see section 2.2.1). Fig. 4.13 shows the corresponding data and linear fits for the central 7 base pairs and the extrapolated lifetimes for 13merRef and 13mer2AP. Lifetimes in green refer to overlap-

**Fig. 4.13:** Basepair lifetime determination. The inversion recovery of imino proton signals is affected by TRIS base which catalyzes exchange with water. The exchange time  $\tau_{ex}$  depends on the inverse base concentration  $1/[B]$ , with different ranges for G:C and A:T pairs. Extrapolation to infinite concentration gives the lifetimes which are collected in the right panel. Lifetimes in green could not be determined separately due to spectral overlap.

ped resonances in the imino proton region. Their overlap is complete and signal recovery identical; therefore only averaged lifetimes can be given. The  $R^2$ -values for all linear fits are above 0.996. Confidence intervals for each lifetime are also determined from the fits. The lifetimes of the terminal base pairs could not be measured due to “base pair fraying” which is commonly observed at the helical termini. Here base pair lifetimes are considerably shortened, broadening the signal from terminal imino protons to the point of vanishing and weakening the signal from neighbouring ones [Leijon and Graslund, 1992, Nonin et al., 1995]. Lifetimes for the semiterminal G:C (0.5 ms) and A:T base pairs (1.1 ms) are found to be identical for 13merRef and 13mer2AP within the estimated error (the corresponding linear plots are shown separately in Fig. 4.15 for reasons of clarity). Contrary to the outer base pairs, lifetimes for the inner seven pairs differ between 13merRef and 13mer2AP. The substitution A→2AP reduces  $\tau_{op}$  severely for the central A:T pairs (by factors 0.55, 0.20 and 0.70 for T21, T20, T19) and less so for the more remote G:C pairs (0.8-0.7).

**Fig. 4.14:** Melting curves via 13mer2AP absorbance (black) and 2AP fluorescence yield (blue points - after heating, red points - after cooling).

**Fig. 4.15:** Linear fits for the imino proton exchange times of T3, T11, G15 and G25 vs the inverse base catalyst concentration.

#### 4.1.2.4 Comparison of duplex melting

Melting curves of 13mer2AP are shown in Fig. 4.14. Black points depict the melting point as determined by following the temperature-dependent absorption at 260 nm. Blue and red points represent duplex melting as determined by monitoring temperature-dependent 2AP fluorescence yield for heating and cooling, respectively. With UV absorption the melting behavior of the entire duplex is monitored whereas the 2AP fluorescence yield is sensitive to the local environment only. Melting points of 59.7 and 59.2 °C for the duplex as a whole and the centre are measured respectively. Thus  $\Delta T_1 = 0.5$  K can be determined for duplex vs centre melting. The melting point of 13merRef was measured as 63.2 °C, with  $\Delta T_2 = 3.5$  K for 13merRef vs 13mer2AP melting.

### 4.1.3 Discussion

#### *Structure perturbation*

Nordlund et al. [1989] studied 2AP in a palindromical decamer sequence. They reported that NOE cross-peaks expected for a regular B-DNA helix, were missing to the 5'-side of the 2AP incorporation site. From that they conclude that the structure is perturbed locally with the perturbation extending only to the adjacent base pairs [Nordlund et al., 1989]. In contrast, all NOE cross-peaks expected for a regular B-DNA helix have been identified for 13mer2AP. This indicates that 2AP incorporation induces no pronounced perturbation in 13mer2AP. A possible explanation might be the higher detection limit of the 600 MHz NMR spectrometer (instead of 300 MHz) and the 5-fold higher duplex concentration employed in this work. Another reason might be the low stability of the decamer duplex, whose melting point decreases by 8.6 K (to 32.8 °C) upon introduction of the two 2AP residues [Nordlund et al., 1989].

The per-atom CSD data analysis for 13merRef and 13mer2AP (cf. section 4.1.2.1) supports the above conclusion that no pronounced perturbation is induced upon 2AP incorporation. Significant per-atom CSDs are observed exclusively between protons spatially adjacent to 2AP in 13mer2AP or A in 13merRef. This suggests that the observed CSDs are due to the different ring current effects induced by 2AP and A [Wijmenga et al., 1997]. Thus per-atom CSD data does not hint at structural differences between the two samples, but instead points to electronic differences between 2AP and A, which are evidenced by quantum chemical calculations [Broo, 1998, Mishra et al., 2000, Jean and Krueger, 2006].

On the contrary, absolute per-residue CSDs indicates that also structural differences exist between 13merRef and 13mer2AP which propagate at least two base pairs in each direction from the modification site. Comparison with the total CSDs between 13merRef and 13merRefGC suggests that the substitution of an A:T by a G:C base pair has a stronger impact on the helical structure than substitution of A by 2AP since total CSDs for the latter are equal or less for the base pairs adjacent to the modification site (cf. Fig. 4.3). This indicates that the helical structures of 13merRef and 13mer2AP both

adopt a regular B-DNA conformation. Yet very subtle structural changes between these two structures exist, which effect the significant CSDs observed for the bases C5 and C9.

A comparison to CSD data on other single mismatch sites is instructive (Note that  $^1\text{H}$ -CSD data for A $\rightarrow$ 2AP substitution, other than reported here, is not available.). Bhattacharya et al. [2002] examined the effect of single mismatches A:A, G:G, C:C on the imino proton chemical shift. CSDs for the adjacent base pairs were significantly more perturbed, than in our case, reflecting the disturbed helical structure resulting from the non-WC-geometries of the mismatch sites. Klewer et al. [2000] studied incorporation of 3-nitropyrrole into DNA. They report CSDs to the unperturbed structure that are comparable to these of 13merRef/13mer2AP. This is surprising given the fact that 3-nitropyrrole is in a syn conformation. Despite this perturbation, the overall helical arrangement is found to be the B-form. This is in line with the results for 13mer2AP, where a B-type helix with small but significant deviations to the structure of 13merRef is suggested by the CSD data.

The overall B-DNA helical structure of 13merRef and 13mer2AP is supported by the calculation results. Slightly smaller RMSDs among the 10 best-energy structures (0.30 and 0.33 Å for 13merRef and 13mer2AP) as compared to the RMSD between the corresponding average structures (0.46 Å) are observed. This indicates that while the overall conformation is identical, minor but significant differences exist. These differences can be visualized by analysing and comparing the helical parameters for 13merRef and 13mer2AP. All of the helical parameters are within the range typically observed for B-DNA (cf. section 2.1). However, significant deviations between 13merRef and 13mer2AP structures exist throughout the duplex (see section 4.1.2.2) for the parameters “Stagger” and “Propeller Twist” between base pair partners, and “Slide” and “Shift” between two base pairs. The largest deviations are observed for the central three base pairs. This is shown in Fig. 4.16 which displays the latter pairs enlarged and from a tilted angle in order to improve visualization of the helical parameters of interest. In conclusion, the structural differences between 13merRef and 13mer2AP are small but detectable.

The structural perturbation induced upon 2AP incorporation is very weak compared

**Fig. 4.16:** Comparison of the three central base pairs (average structures, center of Fig. 4.4 enlarged) for 13mer2AP (yellow) and 13merRef (red). The backbone was omitted for clarity. In the right panel the view was tilted to better visualize the differences in “Shift”- and “Slide”-values.

to other base analogues. Engman et al. investigated the structure of tC containing DNA. They find that the overall B-DNA conformation is preserved. However, the DNA is slightly bent and several NOE cross-peaks involving tC are not consistent with a B-DNA conformation. Furthermore, the second ring of tC, which is not involved in base pairing, extends into the major groove, thus preventing protein docking [Engman et al., 2004]. An even larger fluorophore, pyrene, was used by Smirnov et al. [2002] as a base pair analogue opposite to an abasic site. The overall B-DNA conformation is again preserved, but local mobility or even an alternative orientation of the 5'-adjacent base pair is introduced. This is indicated by the presence of two imino proton signals and very weak or lacking NOE cross-peaks for this base pair [Smirnov et al., 2002]. 2,4-Difluorotoluene - a steric mimic of T devoid of hydrogen bonding sites - was introduced by Guckian et al. [1998]. Although a strong thermodynamic destabilization is found ( $\Delta T=11$  K), no significant deviation of B-DNA conformation is observed as indicated by uninterrupted sequential connectivities. However, a detailed analysis of helical parameters and base pair dynamics is lacking. A whole base pair devoid of hydrogen bonding was used in a related study [Guckian et al., 2000]. It was demonstrated that overall B-DNA conformation is retained. Local mobility however is increased as sensed by broadening of the imino proton resonance at position 5. None of these works use a joint (structure, thermodynamics and base pair kinetics) approach to study perturbation upon incorporation of fluorophores. Moreover, a detailed analysis of helical parameters and a comparison with a control with WC base pairs only is lacking. Thus the present work constitutes a novel approach to the topic of DNA perturbation studies.

#### *Basepair lifetimes*

Although the surrounding structure in 13merRef and 13mer2AP is almost identical, large dynamic differences are indicated by the unusually fast decay of the T20 imino proton diagonal signal in the NOESY-spectrum of 13mer2AP (cf. Fig. 4.11). Inspection of the diagonal signal in NOESY spectra was used by Engman et al. [2004] to qualitatively check for increased water exchange in a modified DNA duplex. The lack of any uncommon phenomena led to the conclusion that base pair dynamics are not perturbed by

#### 4 Results and discussion

incorporation of the fluorophore tC. Following that reasoning, the fast decay observed with the T20 imino proton may indicate increased chemical exchange with water. This interpretation is corroborated by the results of the water saturation transfer experiments. Here the signal of the T20 imino proton is completely cosaturated in 13mer2AP, while the signals from T3 in the same duplex and T20 in the reference duplex are only slightly reduced (Fig. 4.12). Interestingly though, intensities of the adjacent imino protons (T19,T21) are more reduced compared to 13merRef, which indicates faster water exchange for these protons, too. This in turn suggests that 2AP incorporation also effects the dynamics of the adjacent base pairs.

The latter hypothesis has been validated by the results from base pair lifetime measurements. Upon 2AP incorporation the lifetimes of the central seven base pairs seem to be reduced. But the lifetimes of the G4, G10 and G18 imino protons for 13mer2AP and T19 and T20 for 13merRef (shown in green in Fig. 4.13) could not be determined separately due to complete spectral overlap. However their lifetimes should be similar since their recovery behaviour is identical (as assessed by inspection of the 21 1D-spectra resulting from the 21 delay settings after the inversion pulse). Thus the averaged lifetimes can be interpreted for the overlapped protons. Interpretation of differences in base pair lifetimes for the G18, T19 and T21 imino protons of 13merRef and 13mer2AP is complicated as the estimated confidence intervals overlap slightly. However, differences between these lifetimes can be assumed due to the observed reduction of imino proton signal intensity in the water saturation transfer experiment. Additionally, significantly reduced lifetimes for the G4 and G10 imino protons indicate an extended effect of 2AP incorporation on the base pair dynamics of the three adjacent base pairs in each direction. An alternative explanation for the reduced base pair lifetimes of G4 and G10 might be different sample conditions for 13merRef and 13mer2AP. This can be a significant source of errors, when comparing two different samples. However, lifetimes of the base pairs C2:G25, T3:A24,T11:A16, and C12:G15 are equal within the estimated error although these base pairs are influenced by base pair fraying effects. Since the latter effect is sensitive to solution properties (pH, buffer, temperature), different sample conditions

can be ruled out as an explanation. Additionally, the excellent agreement between these lifetimes shows that the lifetime measurements are reliable even below 1 ms. In summary, one can conclude that 2AP incorporation has an extensive, distributed effect on the base pair dynamics of the three adjacent pairs in each direction.

Base pair lifetimes in 2AP-containing DNA have been examined by Lycksell et al. [1987]. Their result for the modification site, of  $1 \pm 2$  ms, agrees qualitatively with the one reported here but is less precise. In contrast, these authors do not observe an extensive, distributed effect on base pair dynamics due to the incorporation of 2AP into the DNA helix. In their palindromic decamer sequence, the melting point is lowered upon incorporation of 2AP from  $41.4^\circ\text{C}$  to  $32.8^\circ\text{C}$  [McLaughlin et al., 1988]. This suggests that at  $25^\circ\text{C}$ , the temperature at which base pair lifetimes were measured, the latter are already affected by duplex melting. This is corroborated by the fact that the opening motion of some inner base pairs is too rapid to be observed. Further support stems from the fact that the central two A:T pairs in their reference sequence constitute an A-tract motif, which would suggest a base pair lifetime for the core A:T pair of over 10 ms [Leroy et al., 1988, Moe and Russu, 1990] rather than 6 ms as observed by Lycksell et al. [1987]. Its length of 13 base pairs makes the non-palindromic duplex studied in the present work thermodynamically more stable. Thus it is less susceptible to destabilization due to base pair fraying. Influence of non-native modifications on the base pair dynamics of adjacent base pairs has been reported in the literature. Moe and Russu [1992] investigated a palindromic dodecamer sequence, with a G:T mismatch introduced at position 4. An increased base pair opening rate is demonstrated for position 5. A similar effect at position 3 could not be resolved due to the high error for the obtained base pair lifetime (60 %) in the reference and signal overlap in the mismatch sequence [Moe and Russu, 1992]. These observations support the finding that 2AP incorporation effects the base pair lifetimes of the three adjacent pairs in each direction.

The extensive, distributed effect of 2AP incorporation on base pair opening dynamics can be explained with transition state theory. For base pair opening to occur, the stabilizing enthalpy contribution from the hydrogen bonds between the partners and the

#### 4 Results and discussion

stacking interaction with the adjacent base pairs have to be overcome when the transition state is formed. Thus a reduction in strength of either interaction would favor base pair opening and thereby lead to a reduced base pair lifetime. Similar reasoning is used to explain the severely reduced base pair lifetimes of the helical termini [Nonin et al., 1995].

Reduced stacking interactions and hydrogen bonding energies throughout the duplex are indicated by the 3.5 K reduction in overall duplex melting temperature upon 2AP incorporation. This is supported by the results of the structural analysis. The higher melting point suggests that stacking interactions and hydrogen bonding in 13merRef are stronger than for 13mer2AP. Thus any change of the position of base pairs (stacking) or base pairing partners (hydrogen bonding) relative to each other must lead to the reduction of either stabilizing energy term. Consequently, the observed deviations in “Stagger” and “Propeller Twist” (defined between base pair partners) on the one hand and “Shift” and “Slide” (defined between base pairs) on the other hand indicate reduced hydrogen bonding and stacking interactions, respectively. Locally, the strong impact of 2AP incorporation on the central three base pairs is indicated by the 0.5 K reduction in duplex melting temperature when monitored via 2AP fluorescence. Since the latter is sensitive only to the directly adjacent base pairs, the observed reduction implies considerable premelting and thus destabilization of the duplex structure around the 2AP modification site as a whole. Premelting around the incorporation site has also been observed by Law et al. [1996] in a 2AP modified undecamer, where the destabilization was found to be even stronger (1.6 K). As pointed out before, deviations in helical parameters are strongest for the central three base pairs, which corroborates the results of the melting study. The latter results are further supported by the fact, that base pair lifetimes are considerably shortened and water saturation transfer is increased for the central three pairs. Thus one can conclude that 2AP incorporation destabilizes the duplex structure, by reducing the stacking and hydrogen bond interactions. This in turn leads to a lower activation enthalpy for the transition state of the base pair opening reaction. Thereby the extensive distributed effect of 2AP incorporation on the base pair lifetimes can be

explained.

The effect of 2AP incorporation on the base pair dynamics of remote pairs can be used to explain results from DNA-protein interaction studies. The latter indicate that although protein activity is reduced, binding affinities are enhanced upon incorporation of 2AP into DNA [Brennan et al., 1986, Petrauskene et al., 1995, Malygin et al., 1999, Reddy and Rao, 2000]. Methyltransferases bind to DNA by flipping the target base out of the helix [Allan and Reich, 1996, Allan et al., 1998, Malygin et al., 1999, Reddy and Rao, 2000]. Thus higher base pair opening rates would enhance this binding process. The latter assumption is supported by the observation of binding enhancement upon introduction of mismatches [Moe and Russu, 1992]. Reddy and Rao [2000] investigated EcoP15I DNA Methyltransferase binding to DNA. They found that binding was enhanced for 2AP-containing DNA as compared to native DNA, regardless, whether 2AP replaces A in the recognition sequence or outside. Similar results were reported by Malygin et al. [1999] for the T4 DAM Methyltransferase. Enhancement of the binding process when 2AP is substituted for an A just outside the recognition center can only be explained by the influence of 2AP substitution on the base pair opening dynamics of several pairs in each direction as was observed for 13mer2AP. Similar observations were made with 2AP-containing DNA binding to restriction endonucleases [Petrauskene et al., 1995, Brennan et al., 1986], which can be explained analogously.

However, the reduced base pair lifetime of 2AP:T cannot account for the increased water exchange in the absence of added catalyst. Despite the fact that in 13mer2AP the base pair lifetimes of A16:T11 (1.1 ms) and A24:T3 (1.0 ms) are significantly smaller than for 2AP:T (1.6 ms), the corresponding imino resonances are still detectable in the presaturation experiment, while that of 2AP:T is missing (see Fig. 4.12). This observation suggests that the short base pair lifetime of 2AP:T accounts only in part for the increased water exchange. Since  $\tau_{op}$  is measured in the limit of high catalyst concentration, but the presaturation experiments were carried out in the absence of catalyst, intrinsic catalysis seems to be involved. One possible catalytic site could be the N1 atom in 2AP, which may have higher basicity compared to A. Electronic differences are indeed

#### 4 Results and discussion

indicated by the CSD data, but it is unlikely that the pK is raised sufficiently high to account for the results. An alternative mechanism involves the T20 O4 atom, which lacks a hydrogen bond to its partner base and can be easily accessed by solvent or base catalyst via the major groove. Thus, by forming a strong hydrogen bond with a potential, effective catalyst, it brings the latter within reach of the imino proton. In this way the catalytic ensemble is preorganised, increasing the probability of the catalytic exchange. Additionally, lack of the sterically demanding amino group in the major groove suggests that for the imino proton to be accessed by the catalyst, full opening of the 2AP:T base pair is not required. Thus exchange catalysis is more effective for 2AP:T as compared to A:T base pairs. Support for this explanation comes from a comparison of  $T_1$ -values in the absence of added catalyst. The latter is shorter by roughly a factor three or more for T20 in 13mer2AP (29.5 ms) when compared to the other T imino protons in the duplex (T3: 199.7 ms, T11: 83.6 ms, T19: 98.8 ms, T21: 141.0 ms).

Another possible explanation for our observations would be exchange from the closed state. Arguments against this possibility are given by Nonin et al. [1995] who find that exchange from the closed state is negligible even for terminal base pairs, since the imino protons are not accessible sideways. The increased exchange rates of terminal imino protons are explained by reduced stacking interactions [Nonin et al., 1995]. Leroy et al. [1993] find that in C:C<sup>+</sup> mispairs the amino protons of C have different exchange times, depending on whether or not they are hydrogen bonded. This supports the conclusion that exchange from the closed state is strongly inhibited when the imino protons are not accessible sideways. The latter is true however for G:T mismatches, where possible exchange from the closed state was discussed by Moe and Russu [1992]. Since sideways accessibility is not the case for 2AP:T base pairs, exchange from the closed state can be ruled out.

The conclusion that the hydrogen bond of the T O4 atom with bulk water or base catalyst increases the efficiency of imino proton exchange is supported by results of Strekowski et al. [1987]. They studied the interaction of DNA with different intercalators and minor groove binders. Regardless of G:C or A:T binding specificity, all molecules contain

ning an amino side chain substituent selectively catalyzed A:T imino proton exchange with bulk water. Analogously to the 2AP:T case, this A:T specificity of can be explained by the formation of a hydrogen bond between the amino side chain of the drug and the T non-hydrogen-bonded O2 atom located in the minor groove. The possibility for this interaction is lacking in G:C base pairs since the formation of three hydrogen bonds leaves no hydrogen-bonding partner available. Thus the formation of this hydrogen bond preorganizes the catalytic ensemble, analogously to what was described for 2AP:T.

## 4.2 2-Hydroxy-7nitrofluorene

### 4.2.1 Introduction

HNF is a fluorene derivative which has been synthesized and incorporated into a DNA double strand only recently [Dallmann et al., 2009]. Consequently, no reports on HNF or HNF-DNA constructs can be found in the literature. For 2AP subtle changes in structure and dynamics had to be analyzed in order to answer the question of applicability to biological systems. In contrast, HNF has been designed for the proof-of-principle that macromolecular vibrational modes can be measured via transient absorption spectroscopy with polarity probes [Dallmann et al., 2009]. Thus the focus of this part of the work is on the position of the fluorophore inside the DNA helix. A comparison of helical parameters with a native structure (as in case of 2AP) is not instructive since HNF is not as close to a natural base pair as 2AP:T.

Compared to 2AP, HNF is much larger in size and thus functions as a base pair surrogate. Due to synthetic reasons the HNF could only be obtained in sufficient purity in the  $\alpha$ -glycosidic form. Preliminary molecular modelling of the HNF-containing duplex with the program HYPERCHEM v7.5 indicated that the hydroxyl linkage introduces orientational flexibility of the HNF moiety. Thus with both,  $\alpha$ - and  $\beta$ -glycosidic form of the HNF nucleotide, stacking of the HNF with its adjacent

base pairs can be realized. The same test calculations suggested that the introduction of an abasic site imposes less steric strain on HNF and prevents the latter (or its partner base) from being flipped out of the helical stack. Thus the same sequence as for 13mer2AP was studied, with the central base pair substituted by **X**=HNF in the left-

**Fig. 4.17:** DNA duplex sequence with chemical structure of the HNF (**X**) and abasic site (**Y**).

hand strand and **Y**=ABA (abasic site) in the other one (cf. Fig. 4.17). A symmetric, nonpalindromic 13 base pair sequence was chosen to dismiss the possibility of mispairing, loop formation and fraying effects. As in 13mer2AP, the central base pair was chosen for modification, in order to avoid fraying effects. The structures and nomenclature of HNF and the abasic site are also depicted in Fig. 4.17. For clarity only hydrogens which are important for the definition of the structure are shown. The nomenclature of the sugar protons follows the one described in section 2.1, with the hydrogen in the  $\beta$ -position of C1' symbolized by H1". Grey numbers indicate the numbering scheme of the carbon atoms and the corresponding hydrogens of the fluorene body (Fig. 4.17).

**Fig. 4.18:** Sequential assignment in the sugar H1' base H6/H8 region of the NOESY-spectrum in  $D_2O$  for 13merHNF. Only the intraresidual cross-peaks H1'-H6/H8 are marked for clarity. Starting points are marked with blue, end points with red circles. Termination points of the sequential assignment within one strand due to the modification site are marked with purple circles.

## 4.2.2 Results

### 4.2.2.1 Chemical shift analysis

The assignment of the DNA signals was achieved following standard procedures as described in Roberts [1993] and Bloomfield et al. [2000]. In contrast to 13mer2AP however, the sequential assignment was interrupted at the modification site due to the lack of base protons at the abasic site (cf. Fig. 4.18, indicated by purple circles). Assignment at the modification site was however possible through several inter- and intrastrand NOE cross-peaks from the HNF H5, H6, H8 and H1, H3, H4 protons to residues T19, ABA20, T21 and A6, A8, respectively. As an example, the NOE cross-peaks A8-H8:HNF7-H1 and A8-H8:HNF7-H3 are marked in Fig. 4.18.

Based on the assignment of the H1' and H6/H8 protons, the remaining base and sugar protons (including HNF and ABA) could be assigned by combining the information from

**Fig. 4.19:** Comparison of the imino proton region of 13merRef, 13merRefGC and 13merHNF. Red solid lines follow the chemical shift assignments of a given imino proton resonance starting from 13merHNF (a) through 13merRef (b) to 13merRefGC (c). The solid green line indicates the chemical shift of the T20 imino proton which does not exist in the 13merHNF duplex.

the COSY-, TOCSY-, HMQC-, and NOESY-spectra. Assignment of the exchangeable protons was done in the WATERGATE-NOESY-spectrum. Because of the symmetry of the sequence the imino, amino, and H2 protons had to be referenced to the already assigned non-exchangeable H5 protons via the H42/H41-H5 NOE cross-peaks. Assignment of the imino protons of T19 and T21 was complicated by the strong upfield shift of both protons when compared to either corresponding protons in 13merRef and 13merRefGC (see Fig. 4.19).

CSD analysis of 13merHNF and the corresponding native structures 13merRef (with a central A:T base pair) and 13merRefGC (with a central G:C base pair) is shown in Fig. 4.20, red and blue columns respectively. For comparison the CSDs between the to native structures 13merRef and 13merRefGC are shown (green columns). The sum of the absolute values of the CSDs for all protons belonging to one residue is given in order to avoid cancelling of negative and positive shifts. This results in a loss of information regarding the direction of the chemical shift differences, but allows for comparison between the different residues. With the exception of the three central base pairs, absolute per-residue CSDs upon introduction of HNF are comparable or only slightly larger than for the exchange of an A:T vs a G:C base pair (Fig. 4.20). Residues that are more

## 4 Results and discussion

**Fig. 4.20:** The sum of the absolute values of the CSDs for all protons belonging to one residue is given for: 13merRef to 13merRefGC (green columns), 13merHNF to 13merRef (red columns) and 13merHNF to 13merRefGC (blue columns). 13merRefGC has the same sequence as 13merRef but with a central G:C base pair.

than two base pairs removed from the modification site do not exhibit significant chemical shift perturbations. The chemical shifts of all assigned proton and carbon atoms for 13merHNF, 13merRefGC and 13merRef are given in the Appendix, sections .6, .7 and .8.

**Fig. 4.21:** The 10 minimum-energy, violation-free structures of 13merHNF in face-up (left panel) and face-down (right panel) orientation are depicted. White arrows indicate the view direction of Fig. 4.23

**Fig. 4.22:** The averaged, minimized structures of 13merHNF in face-up (left panel) and face-down (right panel) orientation are depicted.

#### 4.2.2.2 NMR solution structure

The NMR solution structure is determined from experimental NOE and RDC data as described in section 3.1.4. While we see only one NOE data set for the duplex as a whole, the subset relating to the HNF chromophore cannot be described by a single orientation. Instead two structures of the same duplex are needed with different orientations of the chromophore: one where the fluorene methylene group points towards the major groove (face-up) and one where it points to the minor groove (face-down). Interestingly, the RDC restraints allow both orientations equally well. Simulated Annealing calculations for the two orientations produced two families of structures. The best (minimum-energy, violation-free) 10 of each, which are shown in Fig. 4.21, are used for generating the average structures. The latter are depicted in Fig. 4.22. The HNF probe fits into the helical fold (Fig. 4.21 and 4.22) and stacks with residues 6, 8, 21 and partly 19. This is illustrated in Fig. 4.23, where the central three base pairs of each orientation are zoomed and rotated to visualize stacking interactions.

The calculation results were validated by back-calculation of the NOESY-spectra (red and blue for face-up and face-down orientations respectively) and comparison with the experimental one (green). Fig. 4.24a and 4.24b differ only in the displayed region. While

**Fig. 4.23:** The central three base pairs of the average structures of 13merHNF in face-up (left panel) and face-down (right panel) orientation are depicted.

**Fig. 4.24:** Overlay of the experimental NOESY-spectrum at 150 ms mixing time (green) and the NOESY-spectra back-calculated from the averaged, minimized structures of the HNF in the face-up (blue) and face-down (red) orientation. Arrows point to NOE cross-peaks involving the modification site. Panel (a) depicts the  $H1'-H1/H3$  NOE cross-peaks, which can be only accounted for with the two different orientations of HNF within the double helix. Panel (b) shows the  $H1'-H6/H8$  region, where predicted spectra for both orientations fit the experimental one equally well.

**Fig. 4.25:** Plot of the experimental vs predicted RDCs for 13merHNF with HNF in the face-up (a) and face-down (b) orientations respectively.

the latter shows the H1'-H6/H8 proton region (the same as in Fig. 4.18), Fig. 4.24a centers on two characteristic intraresidual NOE cross-peaks, namely H1/H3-H1" of the HNF residue. The latter peaks can only be accounted for by the two different orientations of the HNF inside the double helix, as is demonstrated by the back-calculated spectra. As either peak would be non-observable with only one orientation sampled, the population ratio of the face-up and face-down orientation can be estimated from the integral ratio of these two peaks to be 1:1. The accuracy of the calculations has been further validated by back-calculation of the RDCs from the average structure. The correlation plots of experimentally determined vs predicted RDCs are shown in Fig. 4.25a (4.25b) and yielded correlation factors ( $R$ ) of 1.000 and q-factors of 0.004 (0.005) for the face-up (face-down) orientations. The precision of the calculations is assessed by the RMSDs of 10 minimum-energy, violation-free structures to their average structure, which are 0.66 Å and 0.47 Å for the face-up and face-down structures, respectively. An analysis of the helical parameters of the duplex structure was not possible since the modification of the central base pair made the definition of the helical axis impossible for the commonly used programs 3DNA [Lu and Olson, 2003] and CURVES+ [Lavery et al., 2009].

**Fig. 4.26:** Absorption changes upon hybridisation, when lowering temperature from 85 to 25°C. The well-known hyperchromism of the UV absorbance (blue arrow) is accompanied by a  $1190\text{ cm}^{-1}$  red-shift of the HNF absorption band.

**Fig. 4.27:** Temperature-dependence of the spectra in Fig. 4.26. The amplitude of the absorption peak around 260 nm (blue points, right scale) yields a melting point of 64°C. The peak position of the HNF absorption band (red points, left scale) shows a melting point which is lower by 3°C.

#### 4.2.2.3 Duplex melting

UV/vis absorption spectra of the DNA-HNF duplex are shown in Fig. 4.26 as a function of temperature. The nucleobases absorb intensely at 260 nm while the HNF chromophore is seen by a weak band around 380 nm, corresponding to the  $S_1 \rightarrow S_0$  transition. At 85°C only single strands are present. As the temperature is lowered to 25°C, the HNF absorption band experiences a red-shift while the nucleobase absorption decreases.

Spectral change with temperature is quantified by "melting curves" as shown in Fig. 4.27. The relative UV absorption amplitude decreases from 1 in the single strands to 0.74 in the duplex (right scale, blue points). A melting point  $T_m$  of 64°C is found for the total concentration  $c_T = 23.5\text{ mM}$  of the single strands. The HNF peak position is shown as red points (left scale) in Fig. 4.27. With this measure the melting point is located 3 K lower.

### 4.2.3 Discussion

Orientational flexibility of the HNF residue is indicated by the existence of two equally strong NOE cross-peaks between the H1'' of the sugar and the H1 and H3 protons, respectively (cf. Fig. 4.24a). From their integrals a 1:1 population ratio could be estimated. Another possible explanation for the observation of a 1:1 integral ratio for these peaks might be spin diffusion effects. This possibility can be ruled out, as the integral ratio exhibited no dependence on the NOESY mixing time parameter. Calculations on both orientations and subsequent spectrum prediction support this conclusion. Interchange between the two orientations of HNF involves a  $180^\circ$  flip around the C1'-O2-bond which links the HNF to the sugar (cf. Fig. 4.17 and 4.22). This can take place only during transient opening of the formal HNF-abasic site base pair. For natural base pairs such opening motions are observed on a millisecond timescale. Another argument for orientational flip on that timescale is that NOE cross-peak signals would appear as an average of both orientations. This might explain why only one NOE data set is observed with some NOE cross-peaks involving the HNF chromophore being exclusively consistent with either orientation and others which can be used to describe both orientations but only with increased error bounds. The consistency of the RDC data with either orientation can be explained by the orientational degeneracy of the small experimental RDC set measured in a single orientational medium (cf. section 2.3.3). Thus one can conclude that the HNF chromophore undergoes orientational flip on a ms timescale.

Possible causes for the orientational degeneracy might be the introduction of the abasic site. The latter has already been reported in the literature to severely increase the flexibility of the helical structure in the vicinity [Coppel et al., 1997, Lin et al., 1998, Hoehn et al., 2001, Lin and de los Santos, 2001, Smirnov et al., 2002, Chen et al., 2007, 2008]. Another reason might be that the HNF chromophore is a conjugated  $\pi$ -system which is largely devoid of functional groups (with the exception of the hydroxyl and the nitro groups at position 2 and 7, respectively). The charge distribution obtained by the DFT calculations described in section 3.1.3 is roughly symmetrical to a  $180^\circ$ -flip around the long HNF axis. Thus no preference in terms of electronic interaction with

#### 4 Results and discussion

the adjacent base pairs can occur.

In both orientations the HNF chromophore intercalates into the DNA double helix despite its  $\alpha$ -glycosidic attachment to the sugar (instead of  $\beta$  for natural nucleotides). This is indicated by the existence of interstrand NOE cross-peaks from the T19, ABA20 and T21 residues to the H5, H6, and H8 protons of HNF as well as the intrastrand ones from the A6 and A8 residues to the H1, H3 and H4 protons. The comparison of the CSD data for 13merHNF, 13merRef and 13merRefGC shows that significant CSDs occur exclusively for the central five base pairs. This suggests that by HNF incorporation the helical structure of the DNA is mainly perturbed two base pairs in each direction while the overall B-DNA conformation remains intact.

Stacking interactions with residues 6, 8, 21 and partly 19 are illustrated in Fig. 4.23. While T21 is fully stacked with the HNF moiety, the T19 residue is turned outward, away from HNF. Thus stacking interactions do not stabilize the T19:A8 base pair as well as the other base pairs. As a consequence the T19 imino proton is shifted up-field and broadened, similar to what is observed with semi-terminal imino protons [Nonin et al., 1995]. This is illustrated by the NMR spectra in Fig. 4.19 where the imino protons of the HNF-substituted duplex (a) are compared to those of the same duplex containing a central A:T (b) or G:C (c) base pair. The T21 imino proton on the other hand, though also shifted upwards significantly, exhibits a very sharp resonance due to the ring current induced by HNF and the stabilizing effect of strong stacking interactions with the latter.

The thermodynamics of duplex formation for 13merHNF has been examined, to probe whether HNF intercalates and how stable the local and global helical arrangement is. When monitored via the temperature-dependent 260 nm absorbance of the nucleobases, a melting point of 64.0 °C is found. A comparison with the melting point of 13merRefGC is instructive. Under the same conditions, it is determined to be  $T_m=69.35$  °C. From a comparison of standard hybridization enthalpies and with the assumption of a common hybridization entropy of -1.2 kJ/mol [Xia et al., 1998], 13merHNF is found to be less stable by 6.9 kJ/mol compared to 13merRefGC. This is equivalent to the lack of enthalpy from hydrogen bonding. When following the red-shift of the absorption band of HNF

at 380 nm, the melting point is estimated at 61.0 °C. The difference in melting points of 3.5 K can be compared to the 0.5 K which are found for the 13mer2AP duplex (see section 4.1.2.4). The large difference found for 13merHNF indicates considerable premelting around the HNF chromophore. This is in line with the results from the structure calculations and chemical shift analysis, which show orientational exchange and less favorable stacking interactions of HNF with T19.

In the past, base pair mimics devoid of hydrogen bonding have been demonstrated to be incorporated by DNA polymerases with comparable efficiency and even higher selectivity than natural bases due to steric complementarity [Morales and Kool, 1998, Guckian et al., 1998, Matray and Kool, 1999, Guckian et al., 2000]. The pyrene nucleotide, for example, can sterically mimic a WC base pair and is incorporated into DNA duplexes opposite to an abasic site without disruption of structure or decrease in duplex stability [Matray and Kool, 1998, Singh et al., 2002, Smirnov et al., 2002]. But pyrene has a pronounced effect on the local dynamics of adjacent base pairs, indicated by the presence of two interconverting resonances for the thymine imino proton to the 5'-side and broadening of the imino proton of the adjacent G:C base pair [Smirnov et al., 2002]. The fact that for the HNF-containing DNA duplex we do not observe interconverting signals, indicates that the perturbation of local dynamics is weaker than for a pyrene residue. However, substantial broadening of the T19 imino proton and orientational flip of the HNF indicate that local flexibility is also induced.

## Summary

Structural and dynamic perturbations in DNA upon incorporation of either fluorophore, 2-Aminopurine (2AP) or 2-Hydroxy-7-nitrofluorene (HNF), are characterized by NMR spectroscopy. For this purpose the NMR solution structures of the modified DNA duplexes with the sequence 5'-GCTGCAXACGTCG-3' are solved. For X=2AP (13mer2AP) the partner base in the complementary strand is T, while for X=HNF (13merHNF) an abasic site is introduced to avoid steric strain.

As a structural isomer of A, the fluorescence properties of 2AP are commonly utilized to monitor stacking-unstacking transitions in molecular biology. By comparing results on 13mer2AP with the corresponding unmodified DNA duplex (13merRef, X=A), any perturbation can be unambiguously assigned to 2AP incorporation. For the NMR solution structure of 13merRef and 13mer2AP small but significant changes in helical parameters are found throughout the helix. Imino proton exchange measurements reveal an extended, distributed effect of 2AP incorporation on the lifetimes of the central seven base pair. This effect is explained by decreased activation enthalpy for base pair opening due to weakened stacking interactions and hydrogen bonding. The latter are indicated by the reduced melting point of 13mer2AP compared to 13merRef. Local melting around the modification site, as sensed by 2AP fluorescence, further supports the results from base pair dynamics. However, the reduced base pair lifetime of 2AP:T cannot fully account for the rapid water exchange observed with saturation transfer experiments in the absence of base catalyst. This indicates enhanced intrinsic catalysis. As a possible catalytic site the T O4 atom opposite 2AP is discussed, which is easily accessible through the major groove and lacks a hydrogen bonding partner within the base pair.

#### 4 Results and discussion

HNF is a fluorene derivative which was designed as a molecular probe for THz vibrational activity in biomolecules. Due to its elongated shape it is introduced opposite to an abasic site, which is known to induce orientational flexibility into DNA helices. The overall NMR solution structure is found to be B-DNA. However the NOE cross-peaks involving the HNF residue can only be accounted for by two different orientations of the HNF inside the DNA helical stack. Their population ratio is estimated to be 1:1. Dynamical perturbation is indicated by the increased linewidth and strong upfield shift of the T residue to the 5'-side of the abasic site. This can be explained with the help of the solution structure, which shows that this T residue cannot stack efficiently with the HNF. Lack of one stacking partner leads to destabilization of the base pair, as is observed for the helical termini.

The dynamic as well as the structural perturbation due to HNF incorporation is large compared to the perturbations induced upon 2AP incorporation. This is not surprising considering the rather artificial shape of HNF as compared to 2AP. Furthermore, 2AP incorporation does not require introduction of an abasic site, which causes orientational flexibility within the double helix. In conclusion, HNF is ill-suited for application to biological problems. Changes observed with 2AP are much smaller. Structural differences are weak but the extended, distributed effect of 2AP incorporation on base pair opening rates limits its value for biologically significant applications such as monitoring stacking-unstacking transitions.

Future development should concentrate on the design of a fluorophore with the demonstrated spectral properties of HNF [Dallmann et al., 2009] but the more native shape of 2AP. For example, the introduction of an electron withdrawing group at the 6-position of 2AP would be an interesting future goal. While a relevant structure (6-Cyano-2-Aminopurine) has already been designed [Hocék and Holý, 1995], attachment to the sugar and incorporation into a DNA sequence have not been demonstrated yet. The introduction of another functional group to 2AP at the 6-position would circumvent the problem of solvent attack and thus reduce the dynamic as well as thermodynamic destabilization.

# Zusammenfassung

Mittels NMR-Spektroskopie werden Störungen in Struktur und Dynamik von DNA untersucht, die durch den Einbau jeweils eines der beiden Fluorophore 2-Aminopurin (2AP) und 2-Hydroxy-7-nitrofluoren (HNF) hervorgerufen werden. Zu diesem Zweck werden die NMR-Strukturen der modifizierten Duplexe mit der Sequenz 5'-GCTGCAXACGTCG-3' berechnet. Im Fall X=2AP (13mer2AP) ist die Partnerbase im Komplementärstrang ein T, während gegenüber X=HNF (13merHNF) eine abasische Stelle eingeführt wird.

Als Strukturisomer von A, werden die Fluoreszenzeigenschaften von 2AP gern genutzt, um stacking-unstacking Übergänge in der Molekularbiologie zu verfolgen. Durch den Vergleich der Ergebnisse zum 13mer2AP mit denjenigen des entsprechenden unmodifizierten DNA Doppelstranges (13merRef, X=A) konnte jegliche Änderung eindeutig dem Einbau von 2AP zugeordnet werden. Für die NMR-Strukturen von 13merRef und 13mer2AP können kleine aber signifikante, über die gesamte Helix verteilte Strukturstörungen nachgewiesen werden. Experimente zum Iminoprotonenaustausch mit Wasser ergeben, daß der Einbau von 2AP die Basenpaarlebensdauern der 7 zentralen Basenpaare erniedrigt. Dieser ausgedehnte Effekt kann durch eine verminderte Aktivierungsenthalpie für die Öffnung des Basenpaares erklärt werden. Ursachen dafür können schwächere Stapelwechselwirkungen und Wasserstoffbrückenbindungen sein. Geringere Energiebeiträge aus letzteren Wechselwirkungen können aus dem niedrigeren Schmelzpunkt des 13mer2AP Duplex abgeschätzt werden. Die DNA Schmelzpunktsbestimmung mittels 2AP-Fluoreszenz deutet lokales Schmelzen um die Modifikationsstelle herum an, was die Ergebnisse zur Basenpaardynamik zusätzlich unterstützt. Die kürzere Lebensdauer des 2AP:T Basenpaares kann jedoch nicht den schnellen Wasseraustausch

#### 4 Results and discussion

im Sättigungstransfer-Experiment ohne Zugabe von Basenkatalysator erklären. Als Erklärung für diese Diskrepanz wird eine effizientere intrinsische Katalyse vermutet. Als mögliche, katalytisch aktive Stelle wird das T O4 Atom diskutiert, welches über die große Furche leicht zugänglich ist und das keine Wasserstoffbrückenbindung innerhalb des Basenpaares ausbilden kann.

HNF ist ein Fluorenderivat das als molekulare Sonde für vibratorische Aktivität von Biomolekülen im THz-Bereich entwickelt wurde. Aufgrund seiner langgestreckten Form, wird statt einer Partnerbase eine abasische Stelle eingesetzt. Von letzterer ist jedoch bekannt, daß sie die helikale Struktur lokal flexibilisiert. Die übergeordnete Struktur des 13merHNF ist eine B-Form DNA Helix. Die NOE Kreuzpeaks zu den Protonen im HNF können jedoch nur durch zwei verschiedene Orientierungen des HNFs in der helikalen Anordnung beschrieben werden. Das Verhältnis der beiden Orientierungen untereinander wird als 1:1 abgeschätzt. Störungen in der Basenpaardynamik werden durch die höhere Linienbreite und die starke Hochfeldverschiebung des T auf der 5'-Seite ausgehend von der abasischen Stelle angedeutet. Eine Erklärung hierfür kann mit Hilfe der berechneten Struktur gegeben werden. Diese zeigt, daß das T keine effektiven Basenstapelwechselwirkungen mit HNF eingehen kann. Das Fehlen eines Wechselwirkungspartners führt zur Destabilisierung des Basenpaares, was z.B. auch für Basenpaare an den Helixtermini beobachtet wird.

Sowohl die dynamischen als auch strukturellen Änderungen nach Einbau von HNF sind groß im Vergleich zu den Störungen die durch den Einbau von 2AP verursacht werden. Eine Erklärung ist die stärkere Abweichung von der Struktur natürlicher Nukleobasen von HNF im Vergleich zu 2AP. Außerdem wird beim Einbau von 2AP keine abasische Stelle im Komplementärstrang benötigt, welche die Flexibilität der DNA-Helix lokal erhöhen würde. Das Fazit ist, das HNF für Anwendungen im biologischen Bereich nicht geeignet ist. Die Änderungen beim Einbau von 2AP sind wesentlich kleiner. Die strukturellen Unterschiede sind schwach, aber der ausgedehnte Effekt des 2AP-Einbaus auf die Basenpaarlebensdauern schränkt die Einsatzmöglichkeiten für biologische Fragestellungen wie stacking-unstacking Übergänge ein.

Die zukünftige Entwicklung neuartiger Fluorophore sollte sich an den bereits demonstrierten spektralen Eigenschaften des HNF [Dallmann et al., 2009] und der deutlich natürlicheren Struktur des 2AP orientieren. Die Einführung einer elektronenziehenden Gruppe in der 6-Position des 2AP stellt ein attraktives Syntheseziel dar. Während eine relevante Struktur (6-Cyano-2-Aminopurine) eines entsprechenden Fluorophores bereits beschrieben wurde [Hocek and Holý, 1995], konnte die glycosidische Verknüpfung und der Einbau in DNA noch nicht realisiert werden. Durch das Einführen einer weiteren funktionellen Gruppe in der 6-Position des 2AP könnte sowohl die dynamische als auch die thermodynamische Destabilisierung verhindert werden.

## .2 Xplor-NIH calculation input files

Since all calculations were carried out under the same conditions, only the input files for the 13mer2AP calculation is shown. The input scripts are based on the example files of the XPLOR-NIH package (refine\_full.py and sa.inp) but were substantially modified in the course of this work. The first script was used to calculate the starting structure for the second script.

```

language
remarks file    nmr/sa.inp
remarks Simulated annealing protocol for NMR structure determination.
remarks The starting structure for this protocol can be any structure with
remarks a reasonable geometry, such as randomly assigned torsion angles or
remarks extended strands.
remarks Author: Michael Nilges

### .3 Xplor-NIH calculation restraints files and structures

The coordinates of the 10 minimum-energy, violation-free structures can be found at the Protein Databank (PDB) with accession codes 2kh0 (13merHNF, face-down), 2kh1 (13merHNF, face-up), 2kz1 (13merRef) and 2kz2 (13mer2AP). The input files to the structure calculations have been deposited along with the structures.

### .4 Lua scripts written for data export from CARA

The following scripts were written for use in CARA only. Their description is given in the header.

```
language
-- script to filter through peaklist with all graded peaks and compare it
-- to normal peaklist. All peaks that are not integrated are written to
-- a new peaklist for inspection.

-- written by Andre Dallmann April-23-2007

## .5 Utility scripts

In this section a short collection of the most frequently used utility scripts is presented. They are grouped according to their function and a small description is supplied.

### Scripts for converting program inputs/outputs for further use in other programs

The next two scripts are used to convert a SPARKY resonance table to a CARA atomlist.

```
language
#!/bin/csh
#
# Skript um aus Sparky-resonance-table eine CARA-atomlist zu machen
#
awk 'NR==1 {print "#Number of dimensions 2"; print "INAME 1 H"; print
      "INAME 2 H"} {print NR-2      "$2"      "$3"      0 U      0.000      0 - 0 }

#!/bin/csh
#
# Skript um aus Sparky-resonance-table eine CARA-atomlist zu machen
#
awk 'NR==1 {gsub (/h2$/,"HQ2",$2); gsub (/h5$/,"HQ5",$7); for (i=1;i<=(NF-1);i++) {printf
      "%5s",toupper($i)}} /me/ {printf "%5s%5s%5s\n", "H71", "H72", "H73"} {if (NR!=1) {print $0"
      "$NF" "$NF"}}' $1.shifts > bla

awk 'BEGIN {COUNT=0} {if (NR==1) {for (i=1;i<=NF;i++) a[i]=$i} else {for (i=2;i<=NF;i++)
      {COUNT++; printf "%s\n",COUNT" "$i" 0.005 "a[i-1]" "NR-1}}}' bla > bla2

awk '{gsub(/g/,"GUA"); gsub(/c/,"CYT"); gsub(/a/,"ADE"); gsub(/t/,"THY"); gsub(/x/,"PUR");
      gsub(/-/,"999"); print}' bla2 > $1_cara.prot
```

The next three scripts are all needed for the NOESY back-calculation with the program GIFA (the first to modify the psf-file, the second to generate the ppm-file needed as input and the last to convert the XPLOR-NIH back-calculation output into GIFA-format.

```
language
#!/bin/csh
#
# Dateiname des PSF-Files ohne Extension muss uebergeben werden.
# Es werden nur CYT,Thy,Ade,Gua selektiert , wenn andere
# Modifikationen vorhanden entsprechend mit einfuehren.
#
awk '{if ((($1~/[0-9]+/)&&($3~/^[a-zA-Z]+$/)&&($3~/^GUA|ADE|CYT|THY|PUR$/)) {$6=".000000";
      $7="1.008"; printf "%14s%-5s%-5s%-5s%-6s%-16s%-7s%12s\n",$1
      " ", $2, $3, $4, $5, $6, $7, $8;
      NR=1} else print}' $1.psf > $1__spect.psf"

#
#
#BEGIN {getline VAR < "'$1'.ppm"; split (VAR,a)}
```

## Script code

```
# if ($4~/^H/) { if ((a[4]==$4)&&(a[2]==$3)) {getline VAR < "'$1'".ppm"; split (VAR,a);
#else {$6=".000000"; $7="1.008"; printf "%14s%-5s%-5s%-5s%-6s%-16s%-7s%12s\n",$1
    ",$2,$3,$4,$5,$6,$7,$8}} else print

#!/bin/csh
#
# Uebergabe des filenames ohne Extension von pdb-file und shifts-file
# Viel Modifizieren nötig, im shifts-file klein h durch goss H ersetzen
# nur A, C, T, G selektiert!!!
# in letzter awk-zeile ist die i<=Zahl anzupassen auf die Zeilenanzahl des ppm-files
awk 'NR==1 {gsub (/h2$/,"HQ2",$2); gsub (/h5$/,"HQ5",$7); for (i=1;i<=(NF-1);i++) {printf
"%5s",toupper($i)}} /me/ {printf "%5s%5s%5s\n","H71","H72","H73"} {if (NR!=1) {print $0"
"NFNF} } $2_2.shifts > bla
awk '{if (NR==1) {for (i=1;i<=NF;i++) a[i]=$i} else {for (i=2;i<=NF;i++) printf "%s\n","PPM
"$1" "NR-1" "a[i-1]" "$i" 1}}' bla > bla2
awk '{gsub (/g[0-9]+/, "GUA"); gsub (/c[0-9]+/, "CYT"); gsub (/a[0-9]+/, "ADE");
    gsub (/t[0-9]+/, "THY"); gsub (/x[0-9]+/, "PUR"); print}' bla2 > bla3
awk '{if ($NF-1)!~/^-$/ print}' bla3 > $1.ppm
#awk '{getline VAR < "'$1'".pdb"; split (VAR,a); store=a[1]; if (a[1]=="ATOM") {store=a[1];
    if ((a[3]==$3)&&($4!~/\-/)) {printf "%s\n",$1" "a[4]" "$2" "$3" "$4" 1; i=1; getline
    VAR < "'$1'".pdb"; split (VAR,a)}}' bla4> $1.ppm
#awk '{if ($1=="ATOM") {if ($3~/^H/) {print} else {getline VAR < "'$1'".ppm"; split (VAR,a);
    for (i=1;i<=211;i++) {if (($4==a[2])&&($5==a[3])&&($3==a[4])) {print; close
    ("'"$1'".ppm"); break} else {getline VAR < "'$1'".ppm"; split (VAR,a)}}; close
    ("'"$1'".ppm")}} else print}' $1.pdb > $1_gifa.pdb
awk '{getline VAR < "'$1'".ppm"; split (VAR,a); for (i=1;i<=211;i++) {if
    (($2==a[2])&&($1==a[3])&&($3==a[4])) {close ("'"$1'".ppm"); for (i=1;i<=211;i++) {if
    (($5==a[2])&&($4==a[3])&&($6==a[4])) {print "INT "$2" "$1" "$3" "$5" "$4" "$6" "$7; close
    ("'"$1'".ppm"); break} else {getline VAR < "'$1'".ppm"; split (VAR,a)}} break} else
    {getline VAR < "'$1'".ppm"; split (VAR,a)}}; close ("'"$1'".ppm")}' $2.spect >
    $2_gifa.spect
rm bla*
```

```
#!/bin/csh
#
# Uebergabe des .spect files ohne Extension
#
set VAR='echo $1'
awk '{if ((NF==9)&&($3~/^(H1[^0-9a-zA-Z]|H2[^0-9a-zA-Z]*|HQ2|HQ5|H3[^0-9a-zA-Z]|H4[^0-9a-zA-Z]|
H5[^0-9a-zA-Z]*|H6|H7[0-9]|H8)$/)&&($6~/^(H1[^0-9a-zA-Z]|H2[^0-9a-zA-Z]*|HQ2|HQ5|H3[^0-9a-zA-Z]|
H4[^0-9a-zA-Z]|H5[^0-9a-zA-Z]*|H6|H7[0-9]|H8)$/)) {printf
"%-4s%-4s%-3s%-5s%-4s%-3s%-5s%-10s\n","INT",$2,$1,$3,$5,$4,$6,$7}}' $VAR.spect >
    $VAR__gifa.spect"
```

The next script is used to generate a latex table from a sparky shifts-file.

```
language
#!/bin/csh
#
# Skript um aus sparky assignment tables tabellen fÄ¼r Latex zu machen
# Es wird der Dateiname des shifts-files mit extension Ä¼bergeben.
#
awk '{if (NR==1) {print " \\arrayrulewidth0.5pt"; print " \\doublerulesep0pt"; print "
    \\begin\\{tabular\\}\\{c|\\|\\|\\|*\\{"(NF-1)"\\}\\{>\\
    {\\PBS\\centering\\}p\\{0.9cm\\}\\|\\}\\>\\{\\PBS\\centering\\}p\\{0.9cm\\}\\}\\}; printf "%s","&"; for
    (i=1;i<=NF;i++) {if (i==NF) {printf "%s","\\textbf\\{"$i"\\}"; printf
```

```
%s\n%s\n", "||||", "\\hline\\hline\\hline"} else printf "%s", "\\textbf{"$i"}\&"} else
{for (i=1;i<=NF;i++) {if (i==1) {printf "%s", "\\textbf{"$i"}\&"} else {if (i==NF)
{printf "%s", $i; printf "%s\n", "||||"} else printf "%s", $i"\&"}}}} $1 > $1\_tab.tex"
```

The next script is used to generate and XPLOR-NIH RDC restraints file from the input to the PALES-program.

```
language
#!/bin/csh
# used to convert pales input to xplor RDC input (with axes2.pdb and axis_500.psf)
awk 'if (NR==1) {print "! RDC table*"; if ((NR>3)&&(NF==10)) {print "assign ( resid 500 and
name OO )\n ( resid 500 and name Z )\n ( resid 500 and name X
)\n ( resid 500 and name Y )\n ( resid "$1" and name "$3"
) ( resid "$1" and name "$6" ) "$ (NF-3)" "$ (NF-2)" "$ (NF-2)" \n\n"}' $1 >
$1".xplor"
```

The next two scripts are used for generating random data subsets from RDC and NOE restraints files, respectively.

```
language
#!/bin/csh
# script to pick out every fourth (or fifth etc) NOE point from input
set VAR='echo $1'
awk 'if ($1~/^assign/) print}' $1 > bla
awk 'BEGIN {DUMMY=5} {if (NR==DUMMY) {DUMMY=DUMMY+3; print > "'$VAR'".unused"} else print}'
    bla > $1.third
rm bla

#!/bin/csh
# script to pick out every fourth (or fifth etc) RDC point from PALES input
set VAR='echo $1'
awk 'BEGIN {DUMMY=6; print "VARS RESID_I RESNAME_I ATOMNAME_I RESID_J RESNAME_J ATOMNAME_J D
DD W\nFORMAT %5d %6s %6s %5d %6s %6s %9.3f %9.3f %.2f" > "'$VAR'".unused"} {if
((NR>3)&&(NR==DUMMY)) {DUMMY=DUMMY+3; print > "'$VAR'".unused"} else print}' $1 >
$1.third
```

The next script is used for generating a single pdb-file from the average and the 10 minimum-energy structures for submission to the PDB databank.

```
language
#!/bin/csh
# script for generating pdb submission file with averaged, minimized structures as model 1
# and the 10 minimum-energy structures as models 2-11. TER cards, chainIDs are inserted
# and ANI residues deleted.
#
set pdbs = 'awk '{if ($1~/pdb/) {printf "%s", $1" "}}' *##_pdb.stats'
cat average_min.pdb $pdbs > bla
awk 'BEGIN {print "MODEL 1"; COUNT1=0; COUNT2=2} {if ($1=="REMARK") print; if
((($1=="ATOM")&&($5<=13)&&($4!="ANI")) {printf
"%-5s%6s%5s%4s%2s%4s%12s%8s%8s%6s%6s%10s\n", $1, $2, $3, $4, "A", $5, $6, $7, $8, $9, $10, "
"; next}; if (($1=="ATOM")&&($5>=14)&&($4!="ANI")) {if (COUNT1==0) {print "TER"; printf
"%-5s%6s%5s%4s%2s%4s%12s%8s%8s%6s%6s%10s\n", $1, $2, $3, $4, "B", $5, $6, $7, $8, $9, $10, "
"; COUNT1=1; next}; if (($1=="END")&&(COUNT2<12)) {printf
"%s\n%s\n%s%9s\n", "TER", "ENDMDL", "MODEL", COUNT2; COUNT2=COUNT2+1; COUNT1=0; next}; if
```

## Script code

```
(( $1=="END" )&&(COUNT2==12)) { printf "%s\n%s\n%s\n", "TER", "ENDMDL", "END" }}' bla >
submit.pdb
#awk 'BEGIN { print "MODEL 1";COUNT1=0;COUNT2=1} { if ($1=="REMARK") print; if
(( $1=="ATOM" )&&($5<=13)&&($4!="ANI" )) { printf
"%5s%-6s%-5s%-4s%-2s%-4s%-12s%-8s%-8s%-6s%-6s%-10s\n", $1, $2, $3, $4, "A", $5, $6, $7, $8, $9, $10, "
"}}' bla > bla2
rm bla
unset pdds
```

The next script calls the program XPLOR-VMD with the 10 minimum-energy structures of a calculation for display.

```
language
#!/bin/csh
# script for displaying top 10 structures of xplor-nih python script in xvmd
set pdds = 'awk '{ if ($1~/pdb/) { printf "%s", $1 " " }}' *##_pdb.stats'
vmd-xplor $pdds
unset pdds
```

The next script collects the CURVES helical parameter calculation out of the 3DNA output files that were generated for the 10 minimum-energy structures of a XPLOR-NIH calculation and prints them to one file.

```
language
#!/bin/csh
#
# Einmaliges Skript zum umnummerieren von schon vorhandenen Dateien
set i=1
while ($i<= 10)
    grep -A 17 "Curves" $i/cf_7methods.par >> comp_hel_par.tab
    @ i++
end
unset i
```

The next script selects just a subset of NOEs from an NOE input file, the rest is commented out.

```
language
#!/bin/csh
#
# uebergabe des .tbl files ohne extension
#
awk '{ if ((( $6~/[hH]1.\)/)&&($11~/[hH]6\)|[hH]8\)/))
|(( ($6~/[hH]6\)|[hH]8\)/)&&($11~/[hH]1.\)/))|((( $6~/^[hH]2[0-9a-zA-Z]\)/)
&&(($11=="H6" )| ( $11=="H8" ) )&&($3=="$8"))|(( $6~/
[hH]2[0-9a-zA-Z][0-9a-zA-Z]\)/)&&(($11=="H6" )| ( $11=="H8" ) )&&($3!="$8"))
{ if ($1=="assign") { printf "%s\n", $0} else { $1="assign"; printf "%s\n", $0}} else
{ $1="!assign"; printf "%s\n", $0}}' $1_2.tbl > bla
awk '$1==$1 { printf "%-9s%-10s%-3s%-4s%-5s%-6s%-10s%-3s%-4s%-5s%-12s%-12s%-8s%-5s%-8s%-4s\n",
$1, $2, $3, $4, $5, $6, $7, $8, $9, $10, $11, $12, $13, $14, $15, $16}' bla > $1_3.tbl
rm bla*
#((( $6~/[hH]6|[hH]8)/)&&($11~/[hH]6|[hH]8)/))|
```

## Scripts for renaming atoms in files

The script is used to rename certain atoms in an input file to XPLOR-NIH calculations.

```

language
#!/bin/csh
sort $2 > bla
sort $1.list > bla2
awk ' $1!="display" {gsub("H5","HQ5",$0);gsub("H2","HQ2",$0);gsub("H7","H7#",$0);print
    $0"\ndisplay \"$result\"}' bla > $2
awk '{gsub("H5","HQ5",$0);gsub("H2","HQ2",$0);gsub("H7","H7#",$0);print $0}' bla2 >
    $1.tbl
rm bla*

```

The script is used to rename certain atoms in a whole family of calculated structures.

```
language
#!/bin/csh
#
#set i=1
#while ($i<= 100)
foreach i (*.pdb)
cp $i bla$i
# sed 's/H2'\''\'' HNF/H2bb HNF/g' $i > "bla"$i
# sed 's/ H2'\'' HNF/H2'\''\''\'' HNF/g' "bla"$i > "blabla"$i
# sed 's/H2bb HNF/ H2'\'' HNF/g' "blabla"$i > "bla"$i
awk '{if (($1=="REMARK")||(($2<208)||($2>235))) {print} else {if ($2==208)
{gsub($2,$2+24);DUMMY1=$0;next};if ($2==209) {gsub($2,$2+24);DUMMY2=$0;next};if
($2==210) {gsub($2,$2+24);DUMMY3=$0;next};if ($2==211)
{gsub($2,$2+24);DUMMY4=$0;next};if (($2>211)&&($2<235)) {gsub($2,$2-4);print;next};if
($2==235) {gsub($2,$2-4);print;print DUMMY1;print DUMMY2;print DUMMY3;print
DUMMY4;next}}}' bla$i > $i
# sed 's/H2'\''\''\'' HNF/H2bb HNF/g' "13mer_HNF_"$i".pdb" > "bla"$i
# sed 's/ H2'\'' HNF/H2'\''\''\'' HNF/g' "bla"$i > "blabla"$i
# sed 's/H2bb HNF/ H2'\'' HNF/g' "blabla"$i > "13mer_HNF_"$i".pdb"
#@ i++
end
rm bla*
```

## Scripts for displaying specific information content from files

This script prints out the number of intra-, interresidual and total number of NOEs, as well as the NOEs to the modification site.

```

language
#!/bin/csh
#
# Skript gibt Anzahl der NOE, der intra- und interresidualen und der NOEs zur Modifikation
# (Achtung nur Position 7) aus
awk 'BEGIN {INTER=0;INTRA=0;MOD=0} {if ($1!="assign") {DUMMY=0} else {if ($3==8)
{INTRA=INTRA+1} else {if (($3==7)||($8==7)) {INTER=INTER+1;MOD=MOD+1} else
{INTER=INTER+1}}}} END {TOTAL=INTER+INTRA; print " Total= "TOTAL; print " intraresidual=
"INTRA; print " interresidual= "INTER; print " NOE to modification site= "MOD}' $1
# || ($3==20) || ($8==20)

```

## Script code

This script prints out the Da and Rh values from all pdb-files in the working directory.

```
language
#!/bin/csh
# script for displaying Da values of top 10 structures of xplor-nih python script
set pdds = 'awk '{if ($1~/pdb/) {printf "%s", $1" "}}' *##_pdb.stats'
grep "Da:" $pdds
unset pdds
```

This script prints out the sorted energies from all pdb-files in the working directory.

```
language
#!/bin/csh
grep "summary total" *.pdb | awk '{print $4" "$5" "$1}' | sort -n
```

This script prints out the sorted energies from just a subset of all pdb-files in the working directory.

```
language
#!/bin/csh
#
# Skript um die 10 niedrigsten Energien auszugeben.
#
set i=1
grep "total" refine*.pdb* | awk '{print $5" "$1" "$2" "$3" "$4}' | sort -n | head -50 | awk
'{print $5" "$1" "$2" "$3" "$4}' | sort -n | head -50 | awk '{print $3" "$4" "$5" "$1"
"$2}' > 50minen
cat 50minen
while ($i<= 50)
    set VAR='awk 'BEGIN {FS="."} {if (NR=="$i") printf "%s", $1}' 50minen'
    cp $VAR".pdb" "min10_"$i".pdb"
    @ i++
end
#rm bla
```

This script generates files which contain the NOE restraints information (which was used as input for the structure calculations) with the corresponding distances in the 10 minimum-energy structures. Thus not only NOE violations but also too tight NOE restraints can be easily identified.

```
language
#!/bin/csh
#
# Skript um die 10 niedrigsten Energien auszugeben.
# Anschliessend werden die Bindungslaengen der 10 energieniedrigsten Strukturen f $\bar{A}$  $\frac{1}{4}$ r die
noe-constraints
# hinter die eingegebenen noe-constraints ausgeschrieben.
# Es muss der Name des noe-constraint-files ohne die extension tbl angegeben werden.
# Es werden mehrere Files ausgegeben die die Auswertung der Strukturen erleichtern
#
set i=1
set VAR='echo $1'
```

```

grep "enviol" *.pdb | awk '{print $3 " $1" " $2" " $4" " $5}' | sort -n | awk '{print $2 " $3"
"$1" " $4" " $5}' | head -10
grep "enviol" *.pdb | awk '{print $3 " $1" " $2" " $4" " $5}' | sort -n | awk '{print $2 " $3"
"$1" " $4" " $5}' | head -10 > blablabla
awk '{printf "%20s%5s%5s%5s", $3-"("$6"/"$8-"("$11,$12,"-$$(NF-1),"+"$NF; if ($1~/^\\!/))
{printf "%5s\\n","off"} else printf "%5s\\n","on"}' $VAR > bla1
cat bla1 > blablal
while ($i<= 10)
    set FILE='awk 'BEGIN {FS="."} {if (NR=="$i") print $1}' blablabla '.noe
    echo $FILE

## Chemical shifts

In the following the chemical shifts are listed. All proton chemical shifts are referenced to the HOD signal at 4.80 ppm.

### .6 Chemical shifts of 13merHNF

The chemical shifts which are unique to HNF and/or the abasic site are not listed in the table and thus are given below in ppm.

HNF (Res 7): H1" 5.32, H4 6.78, C1 109.8, C3 113.7, C4 121.2

Abasic site (Res 20): H1" 4.05

**Tabelle .2:**  $^1\text{H}$  chemical shifts of sugar protons of 13merHNF

# Helical parameter

The averaged values for the 10 minimum-energy, violation-free structures for all helical parameters are listed in the Appendix in sections .11 and .12 for 13merRef and 13mer2AP, respectively. Their RMSD is given as the uncertainty.

## .11 Helical parameters for 13merRef

**Tabelle .14:** *Base pair parameters for 13merRef, translational*

base pair	Shear (Sx)/Å	Stretch (Sy)/Å	Stagger (Sz)/Å

<b>C12–G13</b>	$-0,8 \pm 0,3$	$10,7 \pm 1,6$	$30,6 \pm 0,6$
<b>average</b>	$-0.2 \pm 2.8$	$0.6 \pm 4.3$	$35.7 \pm 3.7$

## List of abbreviations

**WC** Watson-Crick

**DNA** DesoxyriboNucleic Acid

**NMR** Nuclear Magnetic Resonance

**SNP** Single Nnucleotide Polymorphism

**DETEQ** Detection by Electron Transfer controlled Emission Quenching

**FIT** Forced IntercalaTion probe

**FRET** Fluorescence Resonance Excitation Transfer

**2AP** 2-Aminopurin

**HNF** 2-Hydroxy-7-nitrofluorene

**ABA** ABAsic site

**A** Adenine

**T** Thymine

**G** Guanine

**C** Cytosine

**TRIS** Trishydroxymethylaminomethane

**NOE** Nuclear Overhauser Enhancement

*Helical parameter*

**NOESY** Nuclear Overhauser Enhancement Spectroscopy

**ISPA** Isolated Spin Pair Approximation

**RDC** Residual Dipolar Coupling

**PAS** Principle Axis System

**SA** Simulated Annealing

**MD** Molecular Dynamics

**HPLC** High Pressure Liquid Chromatography

**WATERGATE** Water suppression by GrAdient Tailored Excitation

**DQF-COSY** Double Quantum Filtered COrelated Spectroscopy

**TOCSY** TOtal Correlation Spectroscopy

**HMQC** Heteronuclear Multiple Quantum Coherence Spectroscopy

**DFT** Density Functional Theory

**TZVP** Triple Zeta Valence plus Polarization

**MEP** Molecular Electrostatic Potential

**P.E.-COSY** Primitive Exclusive COrelated Spectroscopy

**RMSD** Root Mean Square Deviation

**CSD** Chemical Shift Difference

# Index of figures

1.1	DNA duplex sequence with chemical structure of the 2AP-T and A-T base pairs . . . . .	5
1.2	DNA duplex sequence with chemical structure of the HNF fluorophore and abasic site . . . . .	5
2.1	Structure and nomenclature of the Watson-Crick base pairs A:T and G:C	8
2.2	Nomenclature and structure of 2''-deoxy- $\beta$ -D-ribose . . . . .	9
2.3	Dihedral angles in the sugar-phosphate backbone of DNA . . . . .	9
2.4	Comparison of A- und B-form DNA . . . . .	9
2.5	Helical parameters for the orientational description of base pairs . . . . .	10
2.6	Kinetic scheme of imino proton exchange . . . . .	12
2.7	Scheme of a general inversion recovery pulse sequence . . . . .	18
2.8	Pulse shapes and excitation forms . . . . .	19
2.9	Scheme of a general NOESY pulse sequence . . . . .	21
2.10	The cross-relaxation network of N groups of nuclei . . . . .	22
2.11	Two different approaches to obtain distances from NOE experiments . . .	26
2.12	Steric interaction Pf1-DNA and principle of RDC measurement . . . . .	29
2.13	Orientation of the magnetic field and the internuclear vector in the macromolecular frame . . . . .	31
2.14	Orientation of the internuclear vector in the eigenframe of the alignment tensor and orientational degeneracy of Residual Dipolar Couplings . . . .	33

## Index of figures

3.1	Imino proton signal intensities for the temperature range 283-328 K. in 13mer2AP. . . . .	43
4.1	DNA duplex sequence with chemical structure of the 2AP-T and A-T base pairs . . . . .	57
4.2	Sequential assignment in the sugar H1' base H6/H8 region of the NOESY-spectrum in D <sub>2</sub> O for 13merRef and 13mer2AP . . . . .	62
4.3	Absolute per-residue chemical shift differences of 13mer2AP to 13merRef . . . . .	64
4.4	Structures of 13merRef and 13mer2AP . . . . .	65
4.5	Overlay of the experimental and back-calculated NOESY-spectra . . . . .	66
4.6	Plot of the experimental vs predicted Residual Dipolar Couplings for 13merRef and 13mer2AP . . . . .	66
4.7	13merRef and 13mer2AP: Differences in translational helical parameters between base pair partners . . . . .	67
4.8	13merRef and 13mer2AP: Differences in rotational helical parameter between base pair partners . . . . .	67
4.9	13merRef and 13mer2AP: Differences in translational helical parameter between base pairs . . . . .	68
4.10	13merRef and 13mer2AP: Differences in rotational helical parameter between base pairs . . . . .	68
4.11	T20 and T3 imino proton intensities for 13mer2AP at 298 K . . . . .	71
4.12	Saturation transfer experiments in H <sub>2</sub> O . . . . .	72
4.13	Base pair lifetime determination for 13merRef and 13mer2AP . . . . .	73
4.14	Melting curves via 13mer2AP absorbance and 2AP fluorescence yield. . . . .	74
4.15	Linear fits for the imino proton exchange times of T3,T11,G15 and G25 vs the inverse base catalyst concentration. . . . .	74
4.16	Comparison of the three central base pairs of the average structures for 13merRef and 13mer2AP . . . . .	78
4.17	DNA duplex sequence with chemical structure of the HNF and abasic site . . . . .	86

4.18 Sequential assignment in the sugar H1' base H6/H8 region of the NOESY-spectrum in D <sub>2</sub> O for 13merHNF . . . . .	88
4.19 Comparison of the imino proton region of 13merRef, 13merRefGC and 13merHNF . . . . .	89
4.20 Absolute per-residue chemical shift differences of 13merHNF to the corresponding native structures . . . . .	90
4.21 10 minimum-energy, violation-free structures of 13merHNF in face-up and face-down orientation . . . . .	91
4.22 Averaged, minimized structures of 13merHNF in face-up and face-down orientation . . . . .	91
4.23 Close-up view of the average structures of 13merHNF in face-up and face-down orientation . . . . .	92
4.24 Overlay of the experimental and back-calculated NOESY-spectra for 13merHNF . . . . .	92
4.25 Plot of the experimental vs predicted Residual Dipolar Couplings for 13merHNF . . . . .	93
4.26 Absorption changes upon hybridisation, when lowering temperature from 85 to 25°C for 13merHNF . . . . .	94
4.27 Temperature-dependence of the spectra in Fig. 4.26. . . . .	94

## Index of tables

3.1	Experimentally determined Residual Dipolar Couplings for <i>13merRef</i> . .	48
